ABSTRACT: Theoretical studies from diverse areas of population biology have shown that demographic stochasticity can substantially impact evolutionary dynamics in finite populations, including scenarios where traits that are disfavored by natural selection can nevertheless increase in frequency through the course of evolution. Here, we analytically describe the eco-evolutionary dynamics of finite populations from demographic first principles. We investigate how noise-induced effects can alter the evolutionary fate of populations in which total population size may vary stochastically over time. Starting from a generic birth-death process, we derive a set of stochastic differential equations (SDEs) that describe the eco-evolutionary dynamics of a finite population of individuals bearing discrete traits. Our equations recover well-known descriptions of evolutionary dynamics, such as the replicator-mutator equation, the Price equation, and Fisher's fundamental theorem in the infinite population limit. For finite populations, our SDEs reveal how stochasticity can predictably bias evolutionary trajectories to favor certain traits, a phenomenon we call "noise-induced biasing." We show that noise-induced biasing acts through two distinct mechanisms, which we call the "direct" and "indirect" mechanisms. While the direct mechanism can be identified with classic bet-hedging theory, the indirect mechanism is a more subtle consequence of frequency- and density-dependent demographic stochasticity. Our equations reveal that noise-induced biasing may lead to evolution proceeding in a direction opposite to that predicted by natural selection in the infinite population limit. By extending and generalizing some standard equations of population genetics, we thus describe how demographic stochasticity appears alongside, and interacts with, the more well-understood forces of natural selection and neutral drift to determine the eco-evolutionary dynamics of finite populations of nonconstant size.

Keywords: eco-evolutionary dynamics, finite populations, demographic stochasticity, noise-induced selection, bet hedging, population biology.

Introduction

Eco-evolutionary population biology has a strong mathematical underpinning and can broadly be captured mathematically via a small number of equations, such as the replicator-mutator equation and the Price equation (Page and Nowak 2002; Queller 2017; Lion 2018). The Price equation partitions changes in population composition into multiple terms, each of which lends itself to a straightforward interpretation in terms of the high-level evolutionary forces of selection and mutation, thus providing a useful mathematical framework for describing how populations change over time (Frank 2012). The Price equation also leads to a number of simple yet insightful fundamental theorems of population biology and unifies several seemingly disjointed formal structures under a single theoretical banner (Queller 2017; Lion 2018; Lehtonen 2020a; Luque and Baravalle 2021). However, the replicator-mutator equation, the Price equation, and related fundamental theorems of evolutionary dynamics are usually formulated in a deterministic setting that neglects stochastic fluctuations due to finite population effects (Page and Nowak 2002; Queller 2017; Lion 2018).

Today, we increasingly recognize that incorporating the finite and stochastic nature of the real world routinely has much stronger consequences than simply "adding noise" to deterministic expectations and can cause qualitative changes in the behavior of diverse biological systems (Horstemke and Lefever 1984; Black and McKane 2012; Boettiger 2018; Jhawar et al. 2020; Majumder et al. 2021; DeLong and Cressler 2023; Yamamichi et al. 2023;

Wang et al. 2023). In ecology and evolution, stochastic models need not exhibit phenomena predicted by their deterministic analogues (Proulx and Day 2005; Johansson and Ripa 2006; Black and McKane 2012; Débarre and Otto 2016). They may also exhibit novel phenomena not predicted by deterministic models (Rogers and McKane 2015; Constable et al. 2016; Joshi and Guttal 2018; DeLong and Cressler 2023; Wang et al. 2023).

A striking example of such novel phenomena is the complete “reversal” of evolutionary trajectories (relative to the expectations of infinite population models) that is seen in some finite population eco-evolutionary models (Houchmandzadeh and Vallade 2012; Constable et al. 2016; McLeod and Day 2019a; Mazzolini and Grilli 2023). For example, in public goods games, the production of a costly public good is susceptible to invasion by “cheaters” who use the public good but do not produce it. Because of this, standard (deterministic) evolutionary game theory predicts that producers should eventually become extinct in well-mixed populations. However, in finite fluctuating populations, producers not only persist but also outcompete nonproducers (Constable et al. 2016; McLeod and Day 2019a). This phenomenon of evolution proceeding in the direction of the classically disfavored type that leads to the reversal of the prediction of deterministic natural selection has been dubbed “noise-induced selection” (Week et al. 2021). Noise-induced effects have been seen in several models in fields as diverse as sex chromosome evolution (Veller et al. 2017; Saunders et al. 2018), cell cycle dynamics (Wodarz et al. 2017), social evolution (Houchmandzadeh and Vallade 2012; Chotibut and Nelson 2015; Constable et al. 2016; McLeod and Day 2019a), and epidemiology (Kogan et al. 2014; Humplik et al. 2014; Parsons et al. 2018; McLeod and Day 2019b; Day et al. 2020). Despite the ubiquity of the phenomenon of qualitative noise-induced effects on evolutionary trajectories, we currently lack a description of how classic equations of evolutionary biology, such as the replicator-mutator equation, the Price equation, and Fisher’s fundamental theorem, are affected by such demographic stochasticity.

Two qualitatively different forms of stochasticity are important for eco-evolutionary dynamics—environmental stochasticity from fluctuations in environmental factors such as temperature and precipitation, and demographic stochasticity due to stochasticity in birth and death rates in finite populations (Lande 1993; Shoemaker et al. 2020). Bet-hedging theory, a branch of evolutionary ecology that aims to build general theories that capture the effects of stochasticity on eco-evolutionary dynamics (Seger and Brockmann 1987; Frank and Slatkin 1990; Starrfelt and Kokko 2012), has typically worked with both demographic and environmental stochasticity (Gillespie 1977; Seger and Brockmann 1987; Frank and Slatkin

1990; Olofsson et al. 2009; Childs et al. 2010; Starrfelt and Kokko 2012). On the other hand, models of noise-induced effects and noise-induced selection model stochasticity as arising from the inherent probabilistic nature of birth and death of organisms and are thus concerned only with demographic stochasticity (Parsons et al. 2010; Houchmandzadeh and Vallade 2012; Constable et al. 2016; Parsons et al. 2018; McLeod and Day 2019a; Day et al. 2020). Because of this, it is often unclear *a priori* under what situations these noise-induced effects become important for evolutionary dynamics (Shoemaker et al. 2020; Yamamichi et al. 2023). For example, how does noise-induced selection interact with genetic drift or natural selection? Are noise-induced selection and bet hedging essentially the same effect that has been spoken about using different terminology (Parsons et al. 2010), or are there multiple distinct phenomena at play (Wang et al. 2023)? This article focuses on demographic stochasticity to describe how finite population size can affect eco-evolutionary outcomes.

Specifically, we derive general equations for the dynamics of finite fluctuating populations evolving in continuous time starting from mechanistic first principles via a stochastic birth-death process (fig. 1). By starting from individual-level ecological rules for birth and death and systematically describing population-level dynamics, we relax the assumption of constant (effective) population size that appears in classic finite population models of evolution, such as the Wright-Fisher or Moran models (Lambert 2010; fig. 1). Such a mechanistic approach is also thought to be a more fundamental description of eco-evolutionary dynamics (Lambert 2010; Doebeli et al. 2017). The equations we derive reduce to well-known results, such as the replicator-mutator equation and the Price equation in the infinite population limit, thus illustrating consistency with the known formal structures of eco-evolutionary population dynamics (Queller 2017; Lion 2018). For finite populations, these same equations also provide a generic description and synthesis of the noise-induced effects of finite population size and their consequences for eco-evolutionary population dynamics.

Our systematic derivation provides relations between ecological quantities, such as the expected population growth rate and the variance in population growth rate. Our equations also describe how directional stochastic effects interact with more standard evolutionary forces, such as natural selection and genetic drift. Using these equations, we synthesize the connections between noise-induced effects on population dynamics, including the Gillespie effect of bet-hedging theory (Gillespie 1977), noise-induced effects in ecological population models (Constable et al. 2016; Parsons et al. 2018), drift-induced selection (Veller et al. 2017; Saunders et al. 2018), noise-induced selection

(Week et al. 2021), and the effects of evolutionary noise (McLeod and Day 2019a, 2019b).

A Stochastic Birth-Death Process for Population Dynamics

We consider a well-mixed population that can contain up to m different types of individual entities. For example, a gene may have m different alleles, individuals within a species may come in one of m phenotypes, or a community may have m different species; we refer to each distinct variant of an entity as a “type.” Unlike many classic stochastic formulations in evolutionary theory (Crow and Kimura 1970; Lande 1976; Kimura and Ohta 1974), we do not assume a fixed or deterministically varying (effective) population size. Instead, we allow the total population size to emerge naturally, and thus fluctuate stochastically, from the stochastic birth and death processes (fig. 1).

Description of the Process

A population consisting of up to m different kinds of entities can be completely characterized by specifying the number of individuals of each type of entity. Thus, the state of the population at a given time t is an m -dimensional

vector of the form $\mathbf{n} = [n_1(t), n_2(t), \dots, n_m(t)]^T$, where $n_i(t)$ is the number of individuals of type i . We use $N(t) = \sum_i n_i(t)$ to denote the total population size at time t . Each $n_i(t)$ changes stochastically via a birth-death process, as we describe below. Since $N(t)$ is the sum of m stochastically fluctuating quantities, the total population size $N(t)$ also experiences stochastic fluctuations and is thus nonconstant in our model. We use the term “fluctuating populations” henceforth to refer to populations of nonconstant size that experience stochastic fluctuations in this manner.

We assume that the birth and death rate of each type in the population depends only on the state of the population (the vector \mathbf{n}) and thus neglect any potential contributions from a temporally varying external environment. Our model unfolds in continuous time, and we assume that the probability of two or more births (or deaths) occurring at the same instant is negligible. For each type $i \in \{1, 2, \dots, m\}$, we denote the birth rate and death rate by $b_i(\mathbf{n})$ and $d_i(\mathbf{n})$, respectively. We assume that the birth and death rates at the population level scale with the total population size such that $b_i(\mathbf{n})$ and $d_i(\mathbf{n})$ are of the order of $N(t)$. Furthermore, we assume that there exists a carrying capacity or, more generally, a population size measure (Czuppon and Traulsen

2021) $K > 0$ that imposes a bound on population growth rate such that the growth rate of the total population size $N(t)$ is expected to be negative whenever $N(t) > K$ (box 1).

Given the per capita birth rates $b_i^{(\text{ind})}(\mathbf{x})$ and per capita death rates $d_i^{(\text{ind})}(\mathbf{x})$ of each type (box 1), we define the Malthusian fitness of the i th type as

$$w_i(\mathbf{x}) := b_i^{(\text{ind})}(\mathbf{x}) - d_i^{(\text{ind})}(\mathbf{x}) \quad (1)$$

and the per capita turnover rate of the i th type as

$$\tau_i(\mathbf{x}) := b_i^{(\text{ind})}(\mathbf{x}) + d_i^{(\text{ind})}(\mathbf{x}). \quad (2)$$

The quantity $w_i(\mathbf{x})$ describes the per capita growth rate of type i individuals in a population \mathbf{x} , and $\tau_i(\mathbf{x})$ describes the total rate of stochastic changes (through both births and deaths) to the density of type i individuals. It is notable that both w_i and τ_i depend on the state of the population as a whole (i.e., \mathbf{x}) and not just on the density of the focal type. Thus, in general both the fitness and the turn-

over rate in our model may be both density and frequency dependent.

Fundamental Equations of Eco-Evolutionary Dynamics

Ecological Dynamics: Changes in Population Density

Having described the key demographic processes via a generic birth and death process, we now proceed to understand how the population density vector \mathbf{x} changes over time.

Recall that the stochastic birth-death process changes in units of $1/K$ in density space. Thus, if K is large, each individual contributes a negligible amount to the population density, and the discontinuous jumps due to individual-level births or deaths in units of $1/K$ can be approximated as small continuous changes in population density \mathbf{x} . In section S1 of the supplemental PDF, we use a formal version of this intuitive idea via a system size expansion

Box 1: Assumptions on the birth and death rates

Scaling assumptions. Mathematically, we assume that we can find $\mathcal{O}(1)$ functions $b_i^{(K)}$ and $d_i^{(K)}$ such that we can write

$$\begin{aligned} b_i(\mathbf{n}) &= Kb_i^{(K)}(\mathbf{n}/K), \\ d_i(\mathbf{n}) &= Kd_i^{(K)}(\mathbf{n}/K). \end{aligned} \quad (\text{i})$$

We can now define a notion of population density $\mathbf{x} = \mathbf{n}/K$ by dividing the population number by the population size measure. We assume the stochastic process scales such that population densities remain well defined in the infinite population size limit ($K \rightarrow \infty$). Thus, we consider the limit of infinite population sizes but finite population densities, the usual domain of deterministic equations of population biology, such as the Lotka-Volterra equation and logistic equation. We explain the concept of the infinite population size limit in more detail in section S1.2 of the supplemental PDF.

Functional forms and per capita rates. We assume that the birth and death rate functions have the functional form

$$\begin{aligned} b_i^{(K)}(\mathbf{x}) &= x_i b_i^{(\text{ind})}(\mathbf{x}), \\ d_i^{(K)}(\mathbf{x}) &= x_i d_i^{(\text{ind})}(\mathbf{x}), \end{aligned} \quad (\text{ii})$$

where $b_i^{(\text{ind})}(\mathbf{x})$ and $d_i^{(\text{ind})}(\mathbf{x})$ are nonnegative functions that respectively describe the per capita birth and death rate of type i individuals. In general, the birth rate of type i individuals may contain a component that does not depend purely multiplicatively on the current density x_i of type i : for example, when $x_i = 0$ (i.e., there are no type i individuals in the population), individuals of type i may still be born through mutations of other types or immigration from other sources (gene flow). We account for this possibility via an additional influx term in section S1.1 of the supplemental PDF. Since such an influx term is not majorly affected by stochasticity (sec. S2 of the supplemental PDF), we do not include it in the main text for the sake of conceptual clarity.

We emphasize that these birth and death rates can incorporate complicated interactions, but as we will see, the particular forms of these rate functions do not matter for our purposes as long as the mathematical scaling assumptions in equation (i) are met.

(Ethier and Kurtz 1986, chap. 11; Van Kampen 1981, chap. 10; Black and McKane 2012; Czuppon and Traulsen 2021) to derive a continuous description of the stochastic process for population densities. This continuous description takes the form of an Itô stochastic differential equation (SDE) that says that the density of the i th type changes according to

$$dx_i = x_i w_i(\mathbf{x}) dt + \sqrt{\frac{x_i \tau_i(\mathbf{x})}{K}} dW_t^{(i)}, \quad (3)$$

where each $W_t^{(i)}$ is a one-dimensional Wiener process (standard Brownian motion). Informally, $dW_t^{(i)}$ can be thought of as a normally distributed random variable with mean 0 and variance dt .

The first and second terms on the right-hand side (RHS) of equation (3) respectively provide the so-called infinitesimal mean and infinitesimal variance of the stochastic process $x_i(t)$ that satisfies equation (3) (Karlin and Taylor 1981; Czuppon and Traulsen 2021). Informally, the infinitesimal mean and variance can be understood as follows: if we imagine that the population density of type i changes from x_i to $x_i + dx_i$ over a very small (in-

finitesimal) time interval dt , we can (informally) view dx_i as a random variable. In that case, the expected density change $\mathbb{E}[dx_i]$ and the variance in the change $\mathbb{V}[dx_i]$ are respectively given by

$$\mathbb{E}[dx_i] = x_i w_i(\mathbf{x}), \quad (4a)$$

$$\mathbb{V}[dx_i] = \frac{x_i \tau_i(\mathbf{x})}{K}. \quad (4b)$$

Thus, the Malthusian fitness w_i controls the expected change in population density, whereas the turnover rate τ_i (which is also a measure of the total number of events experienced by type i in a given time interval) controls the variance in the change in population density.

Equation (3) describes the ecological population dynamics. To study the evolutionary dynamics of finite populations, we need to move from population densities to trait frequencies by defining some statistical quantities to describe how traits are distributed in the population (box 2). We will see that this seemingly innocuous observation has important consequences when population size is nonconstant.

Box 2: Statistical measures for population-level quantities

Given any state $\mathbf{x}(t)$ that describes our population at time t , let us first define the total (scaled) population size ($N_K(t)$) and the frequency $p_i(t)$ of each type i in the population at time t as

$$\begin{aligned} N_K(t) &:= \sum_{i=1}^m x_i(t) = \frac{N(t)}{K}, \\ p_i(t) &:= \frac{n_i(t)}{N(t)} = \frac{x_i(t)}{N_K(t)}. \end{aligned} \quad (\text{iii})$$

Here, $N_K(t)$ is an $\mathcal{O}(1)$ quantity, since the total population size $N(t) = KN_K(t)$ is $\mathcal{O}(K)$.

Note that the frequency vector is subject to the constraint $\sum_i p_i = 1$, and we thus only need to study the system using the m variables $[p_1, p_2, \dots, p_{m-1}, N_K]$. We are often interested in tracking the effects of evolution on quantities described at a population level. To facilitate this, let f be any quantity that can be defined at the type level, such as phenotype or fitness, with a (possibly time-dependent) value $f_i \in \mathbb{R}$ for the i th type. Recall that we defined m discrete types in the population on the basis that individuals within each type can be approximated as identical. Now, the statistical mean value of such a quantity in the population $[p_1, p_2, \dots, p_{m-1}]$, which we denote by \bar{f} , is given by

$$\bar{f}(t) := \sum_{i=1}^m f_i p_i, \quad (\text{iv})$$

while the statistical covariance of two such quantities f and g in the population is given by

$$\text{Cov}(f, g) := \bar{fg} - \bar{f}\bar{g}. \quad (\text{v})$$

Last, the statistical variance of a quantity f in the population is given by $\sigma_f^2 := \text{Cov}(f, f)$. It is important to recognize that these statistical quantities are distinct from and independent of the probabilistic expectation, variance, and covariance obtained by integrating over realizations in the underlying probability space. We will denote this latter expectation and variance by $\mathbb{E}[\cdot]$ and $\mathbb{V}[\cdot]$, respectively, for clarity.

Replicator Equation for Finite Fluctuating Populations

We now use Itô calculus to derive equations for the evolutionary dynamics of trait frequencies from equation (3), our SDE for population densities. Letting $\bar{w} = \sum_i w_i p_i$ and $\bar{\tau} = \sum_i \tau_i p_i$ be the average population fitness and the average population turnover respectively, we show in section S2 of the supplemental PDF that p_i , the frequency of the i th type in population $\mathbf{x}(t)$, changes according to the following equation (also see Parsons et al. 2010, eq. [7]; Kuosmanen et al. 2022, eq. [1]):

$$\begin{aligned} dp_i(t) = & \underbrace{(w_i(\mathbf{p}, N_K) - \bar{w})p_i}_{\substack{\text{natural selection} \\ (\text{higher } w \text{ than mean} \\ \text{is better})}} - \underbrace{\frac{1}{KN_K(t)}(\tau_i(\mathbf{p}, N_K) - \bar{\tau})p_i}_{\substack{\text{noise-induced selection} \\ (\text{lower } \tau \text{ than mean is better})}} dt \\ & + \underbrace{\frac{1}{\sqrt{KN_K(t)}} dW_p^{(i)}}_{\substack{\text{stochastic fluctuations} \\ (\text{nondirectional} \\ \text{over small timescales})}}, \end{aligned} \quad (5)$$

where $W_p^{(i)}$ is a stochastic integral term given by

$$dW_p^{(i)} := \sqrt{p_i(1-p_i)^2 \tau_i + p_i^2 \left(\sum_{j \neq i} \tau_j p_j \right)} dW_t^{(i)} \quad (6)$$

and each $W_t^{(i)}$ is a one-dimensional Wiener process. An analogous equation has also been derived for stochastic SIR systems (Parsons et al. 2018, eq. [2.5]). The first term of equation (5) represents the effect of natural selection for increased (Malthusian) fitness. Equation (5), when derived with mutation terms (eq. [S29]), recovers the replicator-mutator equation (eq. [6] in Lion 2018) in the infinite population ($K \rightarrow \infty$) limit (see sec. S7 of the supplemental PDF), and without mutation it recovers the standard replicator equation.

Importantly, finite populations experience a directional force dependent on $\tau_i(\mathbf{x})$, the per capita turnover rate of type i , that cannot be captured in infinite population models but appears in the second term on the RHS of equation (5) (Parsons and Quince 2007; Parsons et al. 2010; Week et al. 2021; Kuosmanen et al. 2022; Bhat 2024). This term shows that the effect of differential turnover rates is mathematically similar to that of differential fitness, but it acts in the opposite direction—a higher relative τ_i leads to a decrease in frequency (notice the minus sign before the second term on the RHS of eq. [5]). For this reason, the effect has been termed “noise-induced selection” (Week et al. 2021), although similar ideas have been known under the names “bet hedging” and “Gillespie effect” in the evolutionary ecology literature (Gillespie 1974, 1977; Frank

and Slatkin 1990; Starrfelt and Kokko 2012; Veller et al. 2017; see box 4). The same effect has also been noticed in the epidemiology literature (Kogan et al. 2014; Parsons et al. 2018; Day et al. 2020). Noise-induced selection can be heuristically understood as a stochastic selection for reduced variance in changes in population density (box 3).

Finally, the last term describes the effects of stochastic fluctuations due to the finite size of the population and shows the $1/\sqrt{KN_K}$ scaling that is typical of demographic stochasticity. Although this last term vanishes upon taking probabilistic expectations (and is hence nondirectional in the short term), it may bias trait frequency distributions by affecting the amount of time spent in different states, as we illustrate in the next section.

To complete the description of the system, we also require an equation for the total scaled population size $N_K = \sum_i x_i$. Upon noting that $dN_K = \sum_i dx_i$, using equation (3) for dx_i and dividing both sides by N_K , we find

$$\frac{1}{N_K} dN_K = \bar{w}(t)dt + \sqrt{\frac{\bar{\tau}(t)}{KN_K(t)}} dW_t^{N_K}, \quad (7)$$

where $W_t^{N_K}$ is a one-dimensional Wiener process and we have used the representation of noise terms presented in section S5 of the supplemental PDF. Thus, fitness affects only the infinitesimal mean, and turnover rate affects only the infinitesimal variance of the total population size. Note that the left-hand side of equation (7) is simply the rate of change of $\log(N_K)$, that is, the rate of change of the (scaled) population size N_K when viewed on a logarithmic scale.

A Special Case: Two Interacting Types. To illustrate the way stochasticity affects evolutionary dynamics in finite fluctuating populations, we consider the simple case of two interacting types (i.e., $m = 2$). Letting $p = p_1$ be the frequency of type 1 individuals in the population, we see from equation (5) that our two-type population obeys the equations

$$\begin{aligned} dp = & \left[(w_1 - w_2)p(1-p) - \frac{1}{KN_K}(\tau_1 - \tau_2)p(1-p) \right] dt \\ & + \frac{1}{\sqrt{KN_K}} \sqrt{p(1-p)[\tau_1 + (\tau_2 - \tau_1)p]} dW_t, \end{aligned} \quad (8a)$$

$$\frac{1}{N_K} dN_K = \bar{w}(t)dt + \sqrt{\frac{\bar{\tau}(t)}{KN_K(t)}} dW_t^{N_K}, \quad (8b)$$

where W_t and $W_t^{N_K}$ are one-dimensional Wiener processes.

We can now identify the (frequency-dependent) selection coefficient $s(p, N_K) := w_1(p, N_K) - w_2(p, N_K)$ from classic population genetics. The selection coefficient quantifies the direction and strength of natural selection in the system—a positive (negative) value of s indicates that

Box 3: A heuristic explanation of noise-induced selection

One key mechanism through which demographic stochasticity can affect evolutionary dynamics is by biasing evolutionary trajectories toward types with lower turnover rates, even if these types have the same (or even lower) fitness than other types in the population. Here, we explain this mechanism via an intuitive argument that has the same flavor as arguments seen in the bet-hedging literature (Gillespie 1977; Frank and Slatkin 1990; Starrfelt and Kokko 2012).

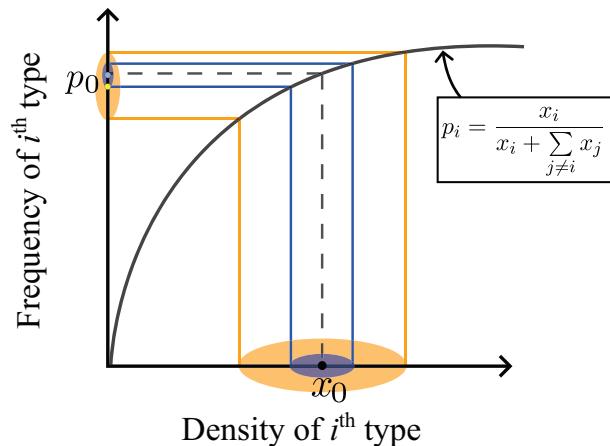

To illustrate the idea via an example, imagine a system consisting of two types of individuals, 1 and 2, that have equal fitness but unequal turnover rates; without loss of generality, assume $\tau_1 > \tau_2$. Let us further assume that both types have the same density x_0 . From equation (4), we see that, in our example, although the two types of individuals have the same expected change in population density, type 1 individuals have a greater variance in the changes in density than type 2 individuals.

Since evolution is defined as changes in trait frequencies, we transform variables from population density to trait frequency to see how differential variance affects evolutionary trajectories. This is done via the transformation

$$p_i = \frac{x_i}{x_i + \sum_{j \neq i} x_j} \quad \text{for any fixed } i \in \{0, 1, 2, \dots, m\}. \quad (\text{vi})$$

Observe now that frequency (p_i) is a concave function of density x_i (eq. [vi]). Due to concavity, equivalent changes in density do not correspond to equivalent changes in frequency. Instead, a result mathematically known as Jensen's inequality and diagrammatically represented in box figure 1 applies.

An increase in density leads to a relatively smaller increase in frequency, whereas an equivalent decrease in density leads to a larger decrease in frequency. This implies that stochastic reductions in density have a higher cost (decrease in frequency) than the benefit (increase in frequency) conferred by a numerically equivalent increase in density (box fig. 1). Thus, variance in the density process leads to a net cost in frequency space, and all else being equal, a greater variance comes with a greater cost. Types with lower turnover rates (corresponding to lower infinitesimal variance in eq. [3]) are thus favored.

Box Figure 1: Diagrammatic representation of the consequences of demographic stochasticity when total population size can vary. The gray curve represents the transformation from population densities to trait frequencies via equation (vi). The ellipses are representations of possible changes in population composition for two types with the same fitness and same initial density but different variances (yellow > blue). The center of the ellipse represents the infinitesimal mean of the density process, the major axis captures the infinitesimal variance, and the colored region is thus representative of all possible changes given that an event (birth or death) has occurred. Reductions in density have a stronger effect on frequency than increases in density, and due to this the expected frequency (centers of ellipses on the y-axis) after an event has occurred is less than the initial frequency p_0 even if the expected density (centers of ellipses on the x-axis) coincides with the initial density x_0 . Types with a larger variance in the density process (yellow ellipse in the figure) experience a greater reduction in expected frequency relative to types with a lower variance (blue ellipse). Similar figures, with the x- and y-axes being absolute fitness and relative fitness, respectively, appear in expositions of bet hedging (e.g., Frank and Slatkin 1990; Starrfelt and Kokko 2012). In our figure, the axes are population density and trait frequency, respectively.

Box 3 (Continued)

The argument we provide here is particular to populations of nonconstant size. To see this, assume that the total (scaled) population size $\sum_i x_i$ is a constant $N > 0$. The transformation in equation (vi) then becomes

$$p_i = \frac{x_i}{x_i + \sum_{j \neq i} x_j} = \frac{x_i}{N} \quad (\text{vii})$$

and is now simply a linear rescaling of x_i . The asymmetry between increases in density and decreases in density thus disappears. In other words, the mechanism that we identified above no longer operates for constant populations.

type 1 individuals are favored (disfavored) by natural selection.

Equation (8a) also motivates the definition of an analogous noise-induced selection coefficient $\kappa(p, N_K) := \tau_2(p, N_K) - \tau_1(p, N_K)$ to quantify the direction and strength of noise-induced selection. If type 1 has a lower turnover rate, $\kappa(p, N_K) > 0$, and thus type 1 is favored by noise-induced selection.

With this notation, equation (8a) becomes

$$\begin{aligned} dp = p(1-p) \left[s(p, N_K) + \frac{\kappa(p, N_K)}{KN_K} \right] dt \\ + \frac{1}{\sqrt{KN_K}} \sqrt{p(1-p)(\tau_1 + p\kappa(p, N_K))} dW_t, \end{aligned} \quad (9)$$

where we see that the selection coefficient $s(p, N_K)$ affects the infinitesimal mean (dt term) of equation (9) and the noise-induced selection coefficient $\kappa(p, N_K)$ affects both the infinitesimal mean and the infinitesimal variance. Note that fitness only enters into the population dynamics via the selection coefficient s , whereas turnover also appears via τ_1 in the second term on the RHS of equation (9). In other words, only the relative fitness or the difference $w_1 - w_2$, but not the absolute value of the fitness w_b , matters for the deterministic dynamics. In contrast, the functional form and absolute value of the per capita turnover rate does affect the stochastic dynamics of the system via the second term on the RHS of equation (9).

Demographic stochasticity can also affect population dynamics through the second term on the RHS of equation (9) due to turnover-dependent stochastic effects (McLeod and Day 2019a). To study these effects, we will examine the speed density m (Karlin and Taylor 1981; Czuppon and Traulsen 2021) of the stochastic process described by equation (9). As we explain in section S6 of the supplemental PDF, the speed density $m(p_0)$ at the point p_0 is a measure of the amount of time the population spends in the “immediate neighborhood” of the state p_0 (formally, it is proportional to the amount of time spent in the interval $(p - \epsilon, p + \epsilon)$ in the limit $\epsilon \rightarrow 0$; see Karlin and Taylor

1981, chap. 15, remark 3.2). When a stationary distribution or quasi-stationary distribution (Collet et al. 2013) exists, it is proportional to the speed density (Karlin and Taylor 1981, chap. 15, eq. [5.34], along with chap. 15, eq. [3.10]; Collet et al. 2013, theorem 6.4), and the speed density thus describes the trait frequency distribution at (quasi) stationarity in such cases. In section S6 of the supplemental PDF, we show (eq. [S83]) that the speed density $m(p)$ obeys the equation

$$\frac{dm}{dp} = m(p) \left[\underbrace{\frac{2p-1}{p(1-p)}}_{\text{antisymmetric about } p=0.5} + \underbrace{\frac{2E(p)}{V(p)}}_{\text{same sign as first term on RHS of eq.(9)}} - \underbrace{\frac{1}{V(p)} \frac{dV}{dp}}_{\text{contributions from second term on RHS of eq. (9)}} \right], \quad (10)$$

where

$$E(p, N_K) = s(p, N_K) + \frac{1}{KN_K} \kappa(p, N_K), \quad (11a)$$

$$V(p, N_K) = \frac{1}{KN_K} (\tau_1(p, N_K) + p\kappa(p, N_K)). \quad (11b)$$

The sign of dm/dp tells us whether the system spends more time in states in which type 1 is overrepresented (positive meaning that type 1 is favored), and the points at which $dm/dp = 0$ tell us about the states that are most likely/least likely to be observed before fixation/extinction has taken place (McLeod and Day 2019a; Majumder et al. 2021). The first term on the RHS of equation (10) is antisymmetric about $p = 0.5$. In other words, if we change p to $(1-p)$ (track type 2 instead of type 1), the term retains the same magnitude but has the opposite sign. Thus, the term does not contribute to directional effects and can be ignored for our purposes. Biologically, the term is smallest at $p = 0.5$ and symmetrically larger as one moves toward the boundaries, and thus it can be thought of as capturing the effect of neutral genetic drift in pushing trait frequency p to the boundaries of $[0, 1]$.

The second term of equation (10) represents the balance between classical selection and noise-induced selection.

Box 4: Two distinct nonneutral effects of demographic stochasticity

Demographic stochasticity can cause certain types to be systematically overrepresented in the population relative to infinite population expectations, even if the fitness of these focal types is the same as (or lower than) the fitness of other types in the population. Since such biases in the trait distribution are induced purely by stochasticity and do not appear in deterministic models, we call this phenomenon “noise-induced biasing.” Our equations reveal that noise-induced biasing can occur through two distinct mechanisms. In this box, we provide a summary of the connections and delineations between the two mechanisms.

1. The direct mechanism selects for reduced variance in changes in population density (Gillespie 1974, 1977). This mechanism appears in the deterministic term (dt term) of the replicator equation (eq. [5]) and is detectable as a systematic deviation of the expected trajectory $\mathbb{E}[dp/dt]$ from the infinite population prediction (Parsons et al. 2010, 2018). The direct mechanism can be identified with the Gillespie effect from the bet-hedging literature (Gillespie 1974) and is obtained as a balance between natural selection for increased ecological growth rate and a stochastic selection for reduced variance in changes in population densities (see box 3). Since the direct mechanism looks mathematically very similar to the force of natural selection (compare the first and second terms on the RHS of eq. [5]), it has also been called “noise-induced selection” in the literature (Week et al. 2021). Noise-induced selection in this sense is thus a version of classical evolutionary bet hedging (Frank and Slatkin 1990; Starrfelt and Kokko 2012) in an explicitly demographic, dynamical context. Note that unlike in bet-hedging models, w and τ (and thus s and κ) are derived from the underlying demographic processes.
2. The indirect mechanism appears as an apparent selection for reduced variance in changes in trait frequency (McLeod and Day 2019a). The effects of demographic stochasticity, in this case, appear in the stochastic term (dW term) of the replicator equation (eq. [5]) and affect the time spent at various configurations and thus, indirectly, the probability of observing a polymorphic population in a particular configuration $(p_1, p_2, \dots, p_{m-1}, N_K)$. The indirect mechanism results from frequency dependence in the variance of changes in trait frequencies and can be thought of as analogous to frequency-dependent viscosity; populations tend to accumulate in those configurations that lead to slower changes in population composition, and we are thus more likely to observe the population in those configurations that make the rate of change of the population slower. The strength of indirect noise-induced biasing varies inversely with (the square root of) population size, and the direction of the effect depends on the frequency dependence of the per capita turnover rates τ_i .

Unlike natural selection, the balance between noise-induced biasing (through either mechanism) and genetic drift in the absence of natural selection does not depend on the total population size. Instead, it is determined by the details of the demographic processes occurring in the population. If different types have different turnover rates, the direct mechanism (noise-induced selection) operates, and if some types are associated with lower variance in the change in trait frequencies, the indirect mechanism operates. Note that this observation means that noise-induced biasing, via both direct and indirect mechanisms, need not operate or be a significant force in small populations, depending on demographic details.

Since both s and κ are $\mathcal{O}(1)$ functions, natural selection will tend to dominate $E(p)$ when the total population size KN_K is large. Additionally, if s and κ are of similar magnitude (i.e., the strength of natural selection is comparable to the strength of the Gillespie effect), natural selection will still dominate the sign of $E(p)$, since the total population size KN_K must be greater than 1. However, noise-induced selection can qualitatively affect evolutionary dynamics if differences in Malthusian fitnesses are close to zero (i.e., natural selection is weak, $|s| \ll 1$) or if total population size KN_K is

small (Parsons et al. 2010, 2018). We also show this explicitly using an example in box 5.

Equation (10) also tells us that noise-induced selection (explained heuristically in box 3) is not the only way in which demographic stochasticity can bias trait distributions. Instead, the speed density is also profoundly affected by the noise terms in equation (9), as captured by the last term on the RHS of equation (10). In particular, even when the first term on the RHS of equation (9) vanishes or acts in the same direction as classical selection,

Box 5: An example: noise-induced biasing with two competing types

Consider a population comprised of two competing types of individuals (denoted 1 and 2). For pedagogical clarity, we assume that the birth and death rates of type 1 are simply shifted from those of type 2 by constants ϵ_b and ϵ_d respectively; that is,

$$b_1^{(\text{ind})}(p, N_K) = b_2^{(\text{ind})}(p, N_K) + \epsilon_b \quad \text{and} \quad d_1^{(\text{ind})}(p, N_K) = d_2^{(\text{ind})}(p, N_K) + \epsilon_d. \quad (\text{viii})$$

We provide potential biological interpretations of this model in terms of either ecological rate modulators (Fronhofer et al. 2023) or competing pathogen strains (Parsons et al. 2018) in section S10 of the supplemental PDF. Using the definitions of the selection coefficient (s) and noise-induced selection coefficient (κ), we find

$$s(p, N_K) = \epsilon_b - \epsilon_d \quad \text{and} \quad \kappa(p, N_K) = -[\epsilon_b + \epsilon_d]. \quad (\text{ix})$$

Equation (ix) shows that all else being equal, reducing the death rate leads to a more favorable evolutionary outcome than increasing the birth rate by the same amount (also see McLeod and Day 2019a; Raatz and Traulsen 2023). We now explain the subtle ways in which demographic stochasticity biases evolutionary dynamics.

Noise-induced biasing in the absence of natural selection. Let us assume that $\epsilon_b = \epsilon_d = \epsilon$. This corresponds to a faster pace of life in type 1 relative to type 2. From equation (ix), we see that $s(p, N_K) = 0$, and thus the two types have equal fitness. In the absence of natural selection, a given initial frequency remains unchanged over time in infinitely large populations. In finite populations experiencing only neutral genetic drift, we expect the probability of fixation of a type to be proportional to its initial frequency. The effects of noise-induced biasing through the direct mechanism (noise-induced selection) can be observed by looking at the change in the expected frequency $\mathbb{E}[p]$, which from equation (9) follows:

$$\frac{d}{dt} \mathbb{E}[p] = \mathbb{E}\left[\frac{\kappa(p, N_K)}{N_K} p(1-p)\right] = -\frac{2\epsilon}{KN_K} \mathbb{E}[p(1-p)]. \quad (\text{x})$$

Since the RHS of equation (x) is always negative for $p \in (0, 1)$, we can infer that the proportion of type 1 individuals is expected to decrease to zero from any initial frequency. Note that unlike for neutral drift, it is always type 2 that is expected to fix. This result is a manifestation of noise-induced selection—all else being equal, a faster pace of life comes with a greater variance in the change of population density within a given time interval, since there are simply more stochastic birth/death events taking place, and types with a slower pace of life (type 2) are thus favored (Parsons and Quince 2007; Parsons et al. 2010; Wodarz et al. 2017).

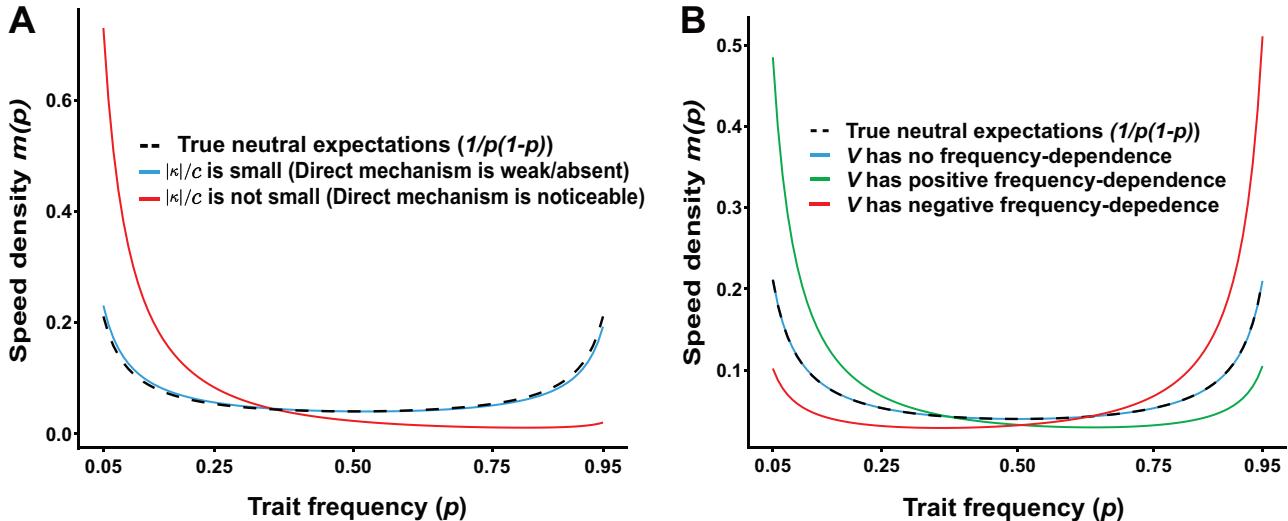

To illustrate the indirect mechanism of noise-induced biasing, we need to assume a functional form for the turnover rates τ_i . In section S10 of the supplemental PDF, we obtain an exact expression for the speed density when $\tau_1 = bp + c$ and $\tau_2 = bp + c - 2\epsilon$ for suitable constants b and c . The parameter c can be viewed as an intrinsic turnover rate, and b can be viewed as a frequency-dependent component that may be either positive or negative. Box figure 2 plots the speed density for various parameter values, illustrating both the direct (box fig. 2A) and the indirect (box fig. 2B) mechanisms of noise-induced biasing. Note that the direct and indirect mechanisms may operate either in isolation or simultaneously and may either supplement (red curve in box fig. 2A and green curve in box fig. 2B) or oppose (red curves in box fig. 2) each other.

Noise-induced biasing in the presence of natural selection. Assume now that $\epsilon_b > \epsilon_d > 0$. In this case, $s > 0$, and thus natural selection favors type 1 individuals. As before, there are two ways in which demographic stochasticity can bias evolutionary dynamics toward certain types. Noise-induced selection could drive the expected trajectory toward fixation of type 2 despite type 1 being favored by natural selection. In section S10 of the supplemental PDF, we show that this can happen if and only if

$$(KN_K - 1)s(p, N_K) = (KN_K - 1)(\epsilon_b - \epsilon_d) < 2\epsilon_d. \quad (\text{xi})$$

Thus, noise-induced selection can reverse the predictions of natural selection when $s(p, N_K)(KN_K - 1)$ is sufficiently small—that is, when natural selection is weak ($s(p, N_K)$ is small), populations are small (KN_K is small), or both. Since the strength and direction of the indirect mechanism depend on the functional form of τ_i , we do not explicitly study it here. However, we provide some preliminary observations in section S10 of the supplemental PDF.

Box 5 (Continued)

Box Figure 2: Two distinct noise-induced effects that bias trait distributions. *A*, If the magnitude of the noise-induced selection coefficient $\kappa = -2\epsilon$ is large relative to the intrinsic turnover rate c , the direct mechanism of noise-induced biasing operates. Parameters are chosen such that $V(p) = \tau_1 + p\kappa = (b - 2\epsilon)p + c$ is not frequency dependent (blue: $\epsilon = 0.5$, $b = 1$, $c = 10$; red: $\epsilon = 0.5$, $b = 1$, $c = 0.5$). *B*, The speed density can also be biased if $V(p)$ is frequency dependent. This indirect mechanism of noise-induced biasing favors the type that reduces $V(p)$. Parameters in this panel are chosen such that $|\kappa|$ is small relative to c and thus the strength of the fast mechanism is negligible (blue: $\epsilon = 0.025$, $b = 0.05$, $c = 10$; green: $\epsilon = 0.025$, $b = 50$, $c = 10$; red: $\epsilon = 0.025$, $b = -8.5$, $c = 10$).

populations may still spend much more time in states where a certain type is overrepresented, in particular possibly reversing the prediction of infinite population models, if dV/dp is nonzero. For example, the system may spend much more time in configurations where type 1 individuals are overrepresented even if $s + \kappa/KN_K < 0$ (meaning that the first term on the RHS of eq. [9] favors type 2 individuals) as long as dV/dp is sufficiently negative (McLeod and Day 2019a). Thus, one type is “favored” through this effect in the sense that we are more likely to observe the population in states where the focal type is overrepresented, an effect that has been ascribed to evolutionary noise (McLeod and Day 2019a, 2019b). As an aside, note that $(1/V)(dV/dp)$ could also equivalently be written as the derivative of $\log(V)$ with respect to p and thus represents the strength and direction of the frequency dependence of $\log(V)$. Since $\mathbb{V}[dp] = p(1-p)V(p)$ from equation (9), $\log(V)$ can be interpreted as being proportional to the logarithm of the variance in the changes in the trait frequency dp . This term thus captures the contributions of stochastic fluctuations (or noise) in the trait frequency changes dp and can be interpreted as selecting for reduced variance in the change in trait frequencies dp , whereas noise-induced selection is a selection for reduced variance in the change in population densities

(box 3). Both of these effects can bias the distribution of types observed in finite populations, and we therefore collectively refer to the two effects as “noise-induced biasing.” Since noise-induced selection is directly visible as a deviation in the expected change in frequency $\mathbb{E}[dp]$, we call it the “direct” mechanism. Since the term looks mathematically similar to the action of natural selection (compare the first and second terms on the RHS of eq. [5] or [9]), we also use the phrase “noise-induced selection” for the direct mechanism (following Week et al. 2021). In contrast, noise-induced biasing via frequency dependence of V is a more subtle mechanism that affects the distribution of types indirectly by biasing the time spent in different states, and we thus refer to this effect as the “indirect” mechanism of noise-induced biasing (box 4).

Remarkably, when natural selection does not operate ($s = 0$), there are situations where the speed density, and thus the stationary distribution when it exists, does not depend on the total population size. In particular, if τ_1 and κ are such that the ratio τ_1/κ is independent of the total population size KN_K , then so is the speed density. Intuitively, this is because both noise-induced biasing and drift arise from the stochasticity associated with finite populations. More precisely, when $s = 0$, the total population size KN_K affects the dynamics only through a prefactor

of $1/KN_K$ that occurs in both $E(p)$ and $V(p)$. It therefore disappears in the ratio E/V . Thus, unlike the classic results regarding natural selection-drift balance, the total population size does not affect the relative strengths of noise-induced biasing and genetic drift—instead, it is the details of the demographic processes, as captured by κ and V , that determine which effect dominates. A similar observation has been made in life history theory (Shpak 2005).

Price Equation for Finite Fluctuating Populations

Having described how the frequencies of types change over time, we now examine the behavior of the statistical population mean \bar{f} of any type-level quantity f (e.g., phenotype, fitness). Classically, the evolution of the statistical mean of a trait in a population is described by the Price equation and related formalisms, such as the breeder's equation (Page and Nowak 2002; Queller 2017; Lehtonen 2018; Lion 2018). Our formalism naturally allows us to extend these results to a stochastic, dynamic setting to describe how mean values change over time in finite fluctuating populations. We find that \bar{f} satisfies the SDE (see sec. S3 of the supplemental PDF)

$$d\bar{f} = \underbrace{\text{Cov}(w, f)dt}_{\text{classical selection}} - \underbrace{\frac{1}{KN_K(t)} \text{Cov}(\tau, f)dt}_{\text{noise-induced selection (direct mechanism)}} + \underbrace{\left(\frac{\partial f}{\partial t} \right) dt}_{\text{effects of changes in trait values } f_i \text{ over time}} + \underbrace{\frac{1}{\sqrt{KN_K(t)}} dW_{\bar{f}}}_{\text{stochastic fluctuations}}, \quad (12)$$

where

$$dW_{\bar{f}} := \left(\sqrt{\text{Cov}(\tau, (f - \bar{f})^2) + \bar{\tau}\sigma_f^2} \right) dW_t \quad (13)$$

is a stochastic integral term describing undirected stochastic fluctuations (see eq. [S67] in sec. S5 of the supplemental PDF). Here, we use W_t to denote a generic Wiener process whose relation to the Wiener processes in equation (5) can be studied using a relation discussed in section S5 of the supplemental PDF. Equation (12) has previously been derived in the epidemiology literature (Day et al. 2020, eq. [5.2]; see sec. S8 in the supplemental PDF), and a quantitative trait version of the equation has also been derived using more sophisticated mathematical techniques (Week et al. 2021, eq. [21b]; Bhat 2024, eq. [25]).

Equation (12) recovers the Price equation (eq. [11] in Lion 2018) in the infinite population ($K \rightarrow \infty$) limit (see

sec. S7 of the supplemental PDF). Each term in equation (12) lends itself to a simple biological interpretation. The first term, $\text{Cov}(w, f)$, is well understood in the classical Price equation and represents the effect of natural selection. If the trait and the fitness are positively correlated, the mean trait value in the population increases due to the effect of selection. The second term, $\text{Cov}(\tau, f)/KN_K(t)$, is the effect of noise-induced selection in finite fluctuating populations. Biologically, the $\text{Cov}(\tau, f)$ term (with negative sign) describes a biasing effect due to differential turnover rates between different types; if the trait is positively correlated with turnover rate, this term causes the mean trait value to decrease.

The third term of equation (12) is relevant whenever f_i can vary over time. Such variation over short (“ecological”) timescales could potentially occur through a changing environment, phenotypic/behavioral plasticity, or any manner of other ecological phenomena that change f_i over time. As we will see in the next section, this term is also responsible for what Fisher called “environmental deterioration” in Fisher's fundamental theorem (Price 1972; Frank and Slatkin 1992).

Finally, the last term of equation (12) describes the role of stochastic fluctuations. Recall that the square of this term corresponds to the infinitesimal variance of the change in the mean value $d\bar{f}$ of the quantity f in the population. The expression $(f_i - \bar{f})^2$ is a measure of the distance of f_i from the population mean \bar{f} . The $\text{Cov}(\tau, (f - \bar{f})^2)$ term thus tells us that if turnover τ_i of the i th type covaries positively with the distance of f_i from the population mean (i.e., individuals with more extreme f have higher turnover rates), the population experiences a greater variance in $d\bar{f}$ (i.e., the change in the mean value of f) over infinitesimal time intervals. The $\bar{\tau}\sigma_f^2$ term tells us that even if τ and f do not covary, there is still some variance in $d\bar{f}$, given now by the product of the mean turnover rate $\bar{\tau}$ with the standing variation σ_f^2 in the quantity f . As we shall see in the next section, this is a manifestation of neutral genetic/ecological drift. Just as in the replicator equation, stochastic fluctuations through $dW_{\bar{f}}$ can profoundly affect the time spent at different values of \bar{f} (and the stationary distribution, when it exists) via the indirect mechanism of noise-induced biasing if the term inside the square root of equation (13) depends on \bar{f} . Note that unlike for the replicator equation, the SDE in equation (12) is one-dimensional regardless of the number of traits (m), and thus the stationary distribution of the mean value \bar{f} can always be studied the way we studied equation (9).

Fisher's Fundamental Theorem for Finite Fluctuating Populations

Two particularly interesting implications of equation (12) are realized upon considering the time evolution of mean

fitness and mean turnover rate. First, upon substituting $f = w$ in equation (12) and taking expectations over the underlying probability space, we obtain

$$\begin{aligned} \mathbb{E}\left[\frac{d\bar{w}}{dt}\right] &= \underbrace{\mathbb{E}[\sigma_w^2]}_{\text{Fisher's fundamental theorem}} - \underbrace{\mathbb{E}\left[\frac{\sigma_{b^{(\text{ind})}}^2 - \sigma_{d^{(\text{ind})}}^2}{KN_K(t)}\right]}_{\text{noise-induced selection}} \\ &\quad + \underbrace{\mathbb{E}\left[\frac{\partial w}{\partial t}\right]}_{\text{eco-evolutionary feedbacks to fitness}}. \end{aligned} \quad (14)$$

The first term, σ_w^2 , is the subject of Fisher's fundamental theorem (Frank and Slatkin 1992; Kokko 2021) and says that in infinite populations, the rate of change of mean fitness in the population is proportional only to the standing variation in fitness σ_w^2 if fitness at the type level (w_i) does not change over time. The second term of equation (14) is a manifestation of noise-induced selection acting and is particular to finite populations (note that the indirect mechanism does not operate because we are only looking at expectation values). Finally, the last term arises whenever w_i can vary over time and represents the effect that Fisher called the "deterioration of the environment" (Price 1972; Frank and Slatkin 1992). In short, this last term captures feedback effects on the fitness w_i of the i th species over short (ecological) timescales (Mylius and Diekmann 1995; Kokko 2021), and we refer the interested reader to Kokko (2021) for a more detailed treatment. Equation (14) recovers the standard version of Fisher's fundamental theorem in the infinite population ($K \rightarrow \infty$) limit (see sec. S7 of the supplemental PDF).

The Demographic Origins of Fitness Differences Induce Quantitative Corrections to Fisher's Fundamental Theorem in Finite Populations. Since $w = b^{(\text{ind})} - d^{(\text{ind})}$ by definition, equation (14) can alternatively be written as

$$\begin{aligned} \mathbb{E}\left[\frac{d\bar{w}}{dt}\right] &= \underbrace{\mathbb{E}\left[\left(1 - \frac{1}{KN_K}\right)\sigma_{b^{(\text{ind})}}^2\right]}_{\text{changes in mean fitness due to variation in birth rates}} + \underbrace{\mathbb{E}\left[\left(1 + \frac{1}{KN_K}\right)\sigma_{d^{(\text{ind})}}^2\right]}_{\text{changes in mean fitness due to variation in death rates}} \\ &\quad + \underbrace{\mathbb{E}\left[\frac{\partial w}{\partial t}\right]}_{\text{eco-evolutionary feedbacks to fitness}}. \end{aligned} \quad (15)$$

Equation (15) redescribes variation in fitness in terms of the more fundamental processes of birth and death. Equation (15) also tells us that variation in death rates leads to a slightly greater rate of increase in mean fitness than an equivalent variation in birth rates. For example, if individuals differ in birth rates alone (i.e., $\sigma_{d^{(\text{ind})}}^2 = 0$, $\sigma_w^2 = \sigma_{b^{(\text{ind})}}^2$), equation (15) predicts that the rate of mean fitness in the absence of eco-evolutionary effects is given by $\mathbb{E}[(1 - 1/KN_K)\sigma_w^2]$. On the other hand, if individuals instead differ in death rates alone (i.e., $\sigma_{b^{(\text{ind})}}^2 = 0$, $\sigma_w^2 = \sigma_{d^{(\text{ind})}}^2$), the rate of change of mean fitness in the absence of eco-evolutionary effects is given by $\mathbb{E}[(1 + 1/KN_K)\sigma_w^2]$, which is a slightly faster rate of change. Note, however, that these are only minor quantitative corrections to Fisher's fundamental theorem, and the two cases exhibit the same qualitative behavior.

An Analog of Fisher's Fundamental Theorem for the Mean Turnover Rate of the Population

Carrying out the same steps in deriving equation (14) with $f = \tau$ in equation (12) yields a dynamical equation for the evolution of mean turnover rates (Kuosmanen et al. 2022) and reads

$$\begin{aligned} \mathbb{E}\left[\frac{d\bar{\tau}}{dt}\right] &= \underbrace{\mathbb{E}\left[\sigma_{b^{(\text{ind})}}^2 - \sigma_{d^{(\text{ind})}}^2\right]}_{\text{natural selection effects}} - \underbrace{\mathbb{E}\left[\frac{\sigma_\tau^2}{KN_K(t)}\right]}_{\text{noise-induced selection effects}} \\ &\quad + \underbrace{\mathbb{E}\left[\frac{\partial \tau}{\partial t}\right]}_{\text{eco-evolutionary feedbacks to } \tau}. \end{aligned} \quad (16)$$

The first term captures the effect of natural selection on mean turnover rates and says that natural selection may either increase or decrease the mean turnover rate depending on the demographic details of the population. More precisely, we predict that natural selection is expected to increase the mean turnover rate in the population if (and only if) the expected variance in the birth rates is greater than the expected variance in the death rates (see also Kuosmanen et al. 2022). The second term of equation (16) represents the effect of noise-induced selection and is exactly analogous to the σ_w^2 term in Fisher's fundamental theorem. This term says that noise-induced selection always reduces mean turnover in the population, with the rate of reduction of the mean turnover rate being proportional to the standing variation in turnover rates σ_τ^2 . Finally, the last term on the RHS of equation (16) quantifies the effect of eco-evolutionary feedback via changes in the turnover of each type over time. In infinitely large populations ($K \rightarrow \infty$), the second term on the RHS of

equation (16) disappears; thus, the mean turnover rate $\bar{\tau}$ may either decrease or increase in infinitely large populations based on demographic details of (the variance of) birth and death rates in the population (Kuosmanen et al. 2022). In contrast, the noise-induced selection (second term) always reduces the mean turnover rate.

The Fundamental Equation for the Population Variance via a Generalization of an Equation for Variance of Type-Level Quantities

Equation (12) is a general equation for the mean value of an arbitrary type-level quantity f in the population. In many real-life situations, we are interested in not just the population mean but also the variance of a quantity in the population. In section S4 of the supplemental PDF, we show that the statistical variance of any type-level quantity f obeys

$$\begin{aligned} d\sigma_f^2 = & \underbrace{\text{Cov}\left(w, (f - \bar{f})^2\right) dt}_{\text{classical selection}} - \underbrace{\frac{2}{KN_K} \text{Cov}\left(\tau, (f - \bar{f})^2\right) dt}_{\text{noise-induced selection}} \\ & - \underbrace{\frac{1}{KN_K} \bar{\tau} \sigma_f^2 dt}_{\text{genetic/ecological drift}} + \underbrace{2\text{Cov}\left(\frac{\partial f}{\partial t}, f\right) dt}_{\text{effects of changes in trait values } f_i \text{ over time}} \\ & + \underbrace{\frac{1}{\sqrt{KN_K(t)}} dW_{\sigma_f^2}}_{\text{stochastic fluctuations}}, \end{aligned} \quad (17)$$

where

$$dW_{\sigma_f^2} := \sqrt{\text{Cov}\left(\tau, (f - \bar{f})^4\right) + \bar{\tau}(\sigma_f^2)^2} dW_t \quad (18)$$

is a stochastic integral term measuring the (nondirectional) effect of stochastic fluctuations that vanishes upon taking an expectation over the probability space (see eq. [S69] in sec. S5 of the supplemental PDF). As before, we use W_t to denote a generic Wiener process—the W_t that appears in equation (17) is not necessarily the same process that appears in either equation (5) or equation (12). The stochastic dependencies between the various Wiener processes can be studied using a relation discussed in section S5 of the supplemental PDF. An infinite population ($K \rightarrow \infty$) version of equation (17) appears in Lion (2018; see sec. S7 of the supplemental PDF) as a dynamic version of earlier, dynamically insufficient equations for the change in trait variation over a single generation (e.g., see eq. [6.14] in Rice 2004).

Once again, the terms of equation (17) lend themselves to straightforward biological interpretation. The quantity

$(f_i - \bar{f})^2$ is a measure of the distance of f_i from the population mean value \bar{f} , and thus covariance with $(f - \bar{f})^2$ quantifies the type of selection operating in the system: a negative correlation is indicative of stabilizing or directional selection, and a positive correlation is indicative of disruptive (i.e., diversifying) selection (Rice 2004, chap. 6; Lion 2018). An extreme case of diversifying selection for fitness occurs if the mean fitness of the population is at a local minimum but $f_i \neq \bar{f}$ (i.e., the population still exhibits some variation in f). In this case, if the variation in f is associated with a variation in fitness, then $\text{Cov}(w, (f - \bar{f})^2)$ is strongly positive and the population experiences a sudden explosion in variance, causing the emergence of polymorphism in the population. If $\text{Cov}(w, (f - \bar{f})^2)$ is still positive after the initial emergence of multiple morphs, evolution eventually leads to the emergence of stable co-existing polymorphisms in the population—this phenomenon is a slight generalization of the idea of evolutionary branching that occurs in frameworks such as adaptive dynamics (Doebeli 2011). The $\text{Cov}(\partial f / \partial t, f)$ term represents the effect of changes in f at the type level over time (due to plasticity, for instance).

Finally, the last term on the RHS of equation (17) describes the role of stochastic fluctuations. The square of this term is the infinitesimal (probabilistic) variance of the changes in statistical variance $d\sigma_f^2$ of f . Just like in the stochastic replicator and Price equations, this term can affect the time spent at different values of trait variance through the indirect mechanism of noise-induced biasing. Just like the stochastic Price equation, the SDE in equation (17) is always one-dimensional, and thus the stationary distribution of the variance σ_f^2 can also always be studied the way we studied equation (9).

In the case of one-dimensional quantitative traits, an infinite-dimensional version of equation (17) has recently been rigorously derived (Week et al. 2021) using measure-theoretic tools under certain additional assumptions (Week et al. 2021, eq. [21c]; see sec. S9 of the supplemental PDF). Taking expectations over the probability space in equation (17) also recovers an equation previously derived and used (Débarre and Otto 2016) in the context of evolutionary branching in finite populations as a special case (eq. [A.23] in Débarre and Otto [2016] is equivalent to our eq. [17] for their choice of functional forms upon converting their change in variance to an infinitesimal rate of change, i.e., derivative).

Loss of Trait Variation in Populations Experiencing Drift. The $\bar{\tau}\sigma_f^2$ term quantifies the loss of variation due to stochastic extinctions (i.e., demographic stochasticity) and thus represents the classic effect of neutral drift in finite populations. Our equations are agnostic to whether each type i is an allele, a phenotype, a morph, or a species, so

the drift in question may be either genetic or ecological drift, depending on the biological context. To see why $\bar{\tau}\sigma_f^2$ quantifies the loss of trait variation, it is instructive to consider the case in which this is the only force at play. Let us imagine a population of asexual organisms in which each f_i is simply a label or mark arbitrarily assigned to individuals in the population at the start of an experiment/observational study and subsequently passed on to offspring—for example, a neutral genetic tag in a part of the genome that experiences a negligible mutation rate. Since the labels are arbitrary and have no effect whatsoever on the biology of the organisms, each label has the same fitness $w_i \equiv w$ and per capita turnover $\tau_i \equiv \tau$, and thus $\bar{w} = w$ and $\bar{\tau} = \tau$. Note that since every type has the same fitness and turnover rate, we have $\text{Cov}(w, (f - \bar{f})^2) \equiv \text{Cov}(\tau, (f - \bar{f})^2) \equiv 0$. Since the labels do not change over time, we also have $\text{Cov}(\partial f / \partial t, f) = 0$. From equation (17), we see that in this case the variance changes as

$$d\sigma_f^2 = -\frac{\tau\sigma_f^2}{KN_K(t)}dt + \frac{1}{\sqrt{KN_K(t)}}dW_{\sigma_f^2}. \quad (19)$$

Taking expectations, the second term on the RHS vanishes, and we see that the expected variance in the population obeys

$$\frac{d\mathbb{E}[\sigma_f^2]}{dt} = -\left(\mathbb{E}\left[\frac{\tau}{KN_K}\right]\right)\mathbb{E}[\sigma_f^2], \quad (20)$$

where we have decomposed the expectation of the product on the RHS into a product of expectations, which is admissible since the label f is completely arbitrary and thus independent of both $\bar{\tau}$ and $N_K(t)$. Equation (20) is a simple linear ODE and has the solution

$$\mathbb{E}[\sigma_f^2](t) = \sigma_f^2(0)e^{-\mathbb{E}[\tau/KN_K]t}. \quad (21)$$

This equation tells us that the expected diversity (variance) of labels in the population decreases exponentially over time. The rate of loss of diversity is $\mathbb{E}[\tau/KN_K]$, and thus populations with a higher turnover rate τ and/or a lower population size KN_K lose diversity faster. This is because populations with higher τ experience more stochastic events per unit time and are thus more prone to stochastic extinction, while extinction is “easier” in smaller populations because a smaller number of deaths is sufficient to eliminate a label from the population completely. Note that which labels/individuals are lost is entirely random (since all labels are arbitrary), but nevertheless labels tend to be stochastically lost until only a single label remains in the population. Upon rescaling time as $t \rightarrow \tau t$, equation (21) recovers the continuous-time version of the loss of heterozygosity formula for finite populations from population genetics (Ewens 2004, eq. [1.5]; Crow and Kimura 1970, secs. 7.3 and 8.4).

Discussion

The central result of our article is a set of stochastic dynamical equations for changes in trait frequencies in the population, equation (5), that generalizes the replicator equation (or, with mutations, the replicator-mutator equation—eq. [S29]) to finite populations of nonconstant size evolving in continuous time. From this, we derive a generalization of the Price equation (eq. [12]) and Fisher’s fundamental theorem (eq. [14]) as well as an equation for changes in population variance of a type-level quantity (eq. [17]). Our equations reveal that demographic stochasticity alone can cause certain types to be more likely to be observed in a population, an effect we term “noise-induced biasing.” Noise-induced biasing can operate through two distinct mechanisms (box 4), one that directly affects the selection term in the replicator equation and another that acts indirectly by affecting the time spent at various states. Several theorists have called for a reformulation of eco-evolutionary dynamics starting from stochastic birth-death processes on the grounds that such a formulation is more fundamental and mechanistic (Metcalf and Pavard 2007; Lambert 2010; Doebeli et al. 2017). Our equations provide a starting point for such a reformulation by deriving some fundamental equations for the eco-evolutionary dynamics of finite, stochastically fluctuating populations.

Finite Population Effects on Eco-Evolutionary Dynamics

Our equations show that noise-induced effects can bias evolutionary outcomes through two major, qualitatively different mechanisms (box 4). The direct mechanism appears in the infinitesimal mean of our SDEs via a noise-induced term that is inversely proportional to the population size (the second term on the RHS of eqq. [5], [12], and [17]). The direct mechanism has previously been reported in various contexts (Parsons and Quince 2007; Parsons et al. 2010; Wodarz et al. 2017; Parsons et al. 2018; Kuosmanen et al. 2022). Since the terms capturing these effects in equations (5), (12), and (17) have the same mathematical form as the effect of classic natural selection, the direct mechanism has previously been referred to as noise-induced selection (Week et al. 2021). It has also been the object of study in early models of bet hedging in finite populations (Gillespie 1974; Gillespie 1977; Shpak 2005), thus explaining why noise-induced selection has previously been associated with the Gillespie effect for reduced variance (Parsons and Quince 2007; Parsons et al. 2010, 2018). However, note that the variance that is studied in bet-hedging models is typically variance in offspring numbers (Gillespie 1977). The variance in equation (4b) is not variance in offspring numbers

but instead variance in the (infinitesimal) ecological growth rate dx_i , a quantity that has sometimes been called “demographic variance” (Engen et al. 1998; Shpak 2007). Furthermore, unlike many classic bet-hedging articles, such as Gillespie (1974), in our framework both w_i and τ_i (and thus the mean and variance of the change in population density) are defined from first principles in terms of birth and death rates (eqq. [1], [2]).

In contrast, the indirect mechanism acts through the infinitesimal variance of our SDEs and thus does not appear in the expected change in trait frequency. This mechanism is a subtle effect of frequency-dependent demographic stochasticity and can be present even when the direct mechanism (i.e., noise-induced selection) is weak or absent (box fig. 2B). Mathematically, the indirect mechanism is revealed as a systematic bias in the speed density that causes the system to spend disproportionately more time in certain states (McLeod and Day 2019a, 2019b; see box 4). If a stationary distribution exists, the indirect mechanism will be visible in the stationary distribution but not in the expected trajectory. The indirect mechanism can be thought of as analogous to frequency-dependent viscosity; populations tend to accumulate in those configurations that lead to slower changes in population composition, and we are thus more likely to observe the population in those configurations that make the rate of change of the population slower. This observation has previously been referred to as the effect of evolutionary noise on evolutionary dynamics (McLeod and Day 2019a, 2019b).

Our results suggest an intriguing requirement for neutral evolution in finite populations. In models of genetic drift, evolution is said to be neutral if the fixation probability of a type in a population is proportional to the initial frequency alone (Ewens 2004). For populations of non-constant size, we see that neutrality in this sense is not ensured if the trait in question is neutral with respect to fitness w alone. Instead, neutral evolution also requires all trait variants to have equal turnover rates, failing which evolution will be quasi neutral and favor those types associated with lower turnover rates (Parsons and Quince 2007; Parsons et al. 2010; Kuosmanen et al. 2022). In other words, even in (finite) populations with no differential fitness among traits, there exists a directional evolutionary force that may systematically bias the course of evolution. Furthermore, the indirect mechanism of noise-induced biasing means that we may be more likely to observe the population in states in which certain types are overrepresented due to a biasing of the speed density and, when it exists, the stationary distribution (McLeod and Day 2019a, 2019b). Thus, even if all individuals in the population have equal fitness and equal turnover, types associated with lower $V(p)$ are still favored in the sense that we are more

likely to observe the population in a configuration at which these types are overrepresented (McLeod and Day 2019a, 2019b) relative to neutral expectations, as defined above. However, it may be noted that the strength of noise-induced biasing is likely to be small or even negligible unless the population size is sufficiently small and/or all types in the population have close to equal fitness (i.e., natural selection is weak).

In our model, noise-induced selection is particular to fluctuating populations and does not occur in models with fixed population sizes, such as the Wright-Fisher or Moran models (box 3). Taken alongside other theoretical (Lambert 2010; Parsons et al. 2010; Abu Awad and Coron 2018; Kuosmanen et al. 2022; Mazzolini and Grilli 2023) and empirical (Papkou et al. 2016; Chavhan et al. 2019) studies of evolution in fluctuating populations, this last point suggests that models that assume fixed total population size, such as Wright-Fisher and Moran, may miss out on important evolutionary phenomena that are seen only in finite populations of nonconstant size. We explain how our framework incorporates the drift-induced selection from sex chromosome evolution (Veller et al. 2017; Saunders et al. 2018) as well as some previous studies from social evolution (McLeod and Day 2019a) and epidemiology (Parsons et al. 2018; Day et al. 2020) in section S8 of the supplemental PDF. We also explain connections with some other general frameworks of eco-evolutionary dynamics (Rice 2020; Week et al. 2021; Kuosmanen et al. 2022) in section S9 of the supplemental PDF.

Concluding Remarks

A growing body of literature has begun to highlight the surprising and counterintuitive effects of demographic stochasticity in shaping evolutionary outcomes in many ecological scenarios. In this article, we derive from first principles stochastic dynamical equations for eco-evolutionary dynamics that generalize some standard equations of population biology, thus providing a conceptual synthesis of the findings of these previous studies. The terms of the equations we derive lend themselves to simple biological interpretations and recover standard equations of evolutionary theory in the infinite population limit. To the best of our knowledge, the equations we derive in this article are the first to showcase how demographic stochasticity generically alters some standard equations of population biology. The utility of the equations we derive thus lies not (necessarily) in their solutions for specific models but instead in their generality and the fact that their terms help us clearly think about the various evolutionary phenomena operating in biological populations (Queller 2017; Lehtonen 2018; Lion 2018; Luque and Baravalle 2021). The direct and indirect mechanisms of noise-induced biasing

have distinct origins, may operate either independently or together, and may push evolution in different directions (see the example in box 5). It is therefore essential that studies explicitly differentiate between these two mechanisms to identify which noise-induced effects are germane to any particular biological population (box 4). By rederiving some standard equations of population dynamics for finite populations, we provide a framework with which to approach particular finite population systems and systematically determine which evolutionary forces are important from demographic first principles.

Although we neglect environmental stochasticity in our current work, populations that experience both environmental and demographic stochasticity often exhibit surprising and counterintuitive eco-evolutionary dynamics (Gokhale and Hauert 2016; Chavhan et al. 2021). Studying the interplay of noise-induced biasing with environmental stochasticity may thus present a promising avenue for future work. Since both the strength (Hamilton 1966; Mallet et al. 2011; Lehtonen 2020b) and the direction (Chapman et al. 2003; Maklakov and Chapman 2019) of natural selection may vary in populations structured by classes such as age or sex, extending our model to include population structure could also be fruitful. On the empirical side, developing methods to disentangle different demographic stochastic effects from empirical datasets could be another interesting avenue for future work.

S1 The master equation and the system size expansion

Given a system with m different types of individuals and birth and death rate functions $b_i(\mathbf{n})$ and $d_i(\mathbf{n})$, we are interested in finding an equation for the rate of change of the conditional probability $P(\mathbf{n}, t | \mathbf{n}_0, 0)$, the probability of finding the population in a state \mathbf{n} at time t . Henceforth, we omit the conditioning for notational brevity and simply write $P(\mathbf{n}, t)$ for this quantity. We assume that the birth and death rates are of the order of the total population size, *i.e.* that $b_i(\mathbf{n})$ and $d_i(\mathbf{n})$ are $\mathcal{O}(\sum_i n_i)$ functions.

For each $i \in \{1, \dots, m\}$, let us now define two step operators \mathcal{E}_i^\pm by their action on any function $f([n_1, \dots, n_m], t)$ as:

$$\mathcal{E}_i^\pm f([n_1, \dots, n_i, \dots, n_m], t) = f([n_1, \dots, n_i \pm 1, \dots, n_m], t) \quad (\text{S1})$$

In other words, \mathcal{E}_i^\pm just changes the population through the addition or removal of one type i individual. We can now write down an exact equation for the rate of change of $P(\mathbf{n}, t)$ by noting that the only direct transitions allowed are those from populations that are exactly one individual away from our focal population. Thus, we have the relation

$$\frac{\partial P}{\partial t}(\mathbf{n}, t) = \sum_{j=1}^m \left[(\mathcal{E}_j^- - 1)b_j(\mathbf{n})P(\mathbf{n}, t) + (\mathcal{E}_j^+ - 1)d_j(\mathbf{n})P(\mathbf{n}, t) \right] \quad (\text{S2})$$

This equation is called the ‘master equation’, and completely characterizes our m -dimensional process.

S1.1 Scaling assumptions, functional forms of birth and death rates

As mentioned in the main text, we assume that there is a carrying capacity/population size measure $K > 0$ such that the total population size $\sum_i n_i$ is expected to be $\mathcal{O}(K)$. This allows us to move from population numbers \mathbf{n} to population ‘densities’ $\mathbf{x} = \mathbf{n}/K$. Specifically, we assume that we can

find $\mathcal{O}(1)$ functions $b_i^{(K)}$ and $d_i^{(K)}$ such that we can write

$$\begin{aligned} b_i(\mathbf{n}) &= Kb_i^{(K)}(\mathbf{x}) \\ d_i(\mathbf{n}) &= Kd_i^{(K)}(\mathbf{x}) \end{aligned} \tag{S3}$$

Note that this assumption means that $b_i^{(K)}$ and $d_i^{(K)}$ remain well-defined even in the $K \rightarrow \infty$ limit, since b_i/K and d_i/K remain $\mathcal{O}(1)$ by our assumption on the scaling properties of \mathbf{n} , b_i , and d_i . Thus, we may still speak of population densities x in the infinite population size limit ($K \rightarrow \infty$). Note that this scaling assumption implies that in the functional forms S4, we assume that $b_i^{(\text{ind})}(\mathbf{x})$, $d_i^{(\text{ind})}(\mathbf{x})$, and $Q_i(\mathbf{x})$ are all $\mathcal{O}(1)$ functions.

In the supplementary, we assume birth and death rates have the slightly more general functional form

$$\begin{aligned} b_i^{(K)}(\mathbf{x}) &= x_i b_i^{(\text{ind})}(\mathbf{x}) + \lambda Q_i(\mathbf{x}) \\ d_i^{(K)}(\mathbf{x}) &= x_i d_i^{(\text{ind})}(\mathbf{x}) \end{aligned} \tag{S4}$$

where, as defined in the main text, $b_i^{(\text{ind})}(\mathbf{x})$ and $d_i^{(\text{ind})}(\mathbf{x})$ are non-negative functions that describe the per-capita birth and death rate of type i individuals, respectively. When there are no type i individuals in the population ($x_i = 0$), individuals of type i may still be born through mutations of other types or via immigration from other sources (gene flow). Thus, the birth rate of type i may contain terms that do not depend multiplicatively on the density x_i of type i individuals. The term $\lambda Q_i(\mathbf{x})$ accounts for this possibility. The equations in the main text are recovered upon removing this term by setting $\lambda = 0$.

The term λQ_i in Eq. S4 thus models an influx of type i individuals from sources other than the existing pool of type i individuals. Here, $\lambda \geq 0$ is a constant describing the rate of influx of type i individuals from sources other than the existing pool of type i individuals, and $Q_i(\mathbf{x})$ is a non-negative function that describes this additional contribution. For example, if type i individuals can arise due to mutations of offspring of other types of individuals during birth, λ would represent a mutation rate (typically denoted by μ) and Q_i would model the functional form of mutation. A

common choice, for example, is $Q_i(\mathbf{x}) = \sum_{j \neq i} x_j$ (*i.e.* the mutation $j \rightarrow i$ occurs at a total rate of μx_j). The influx term could also model immigration of type i individuals from other populations since such immigration would depend not on the density of individuals x_i in our focal population, but on the density of individuals in the ‘source population’ from which individuals are emigrating into our focal population. In this latter case, λ would represent a dispersal rate and Q_i would model the dispersal. Note that no analogous problem exists for the death rate, since the death rate of type i individuals must be 0 when x_i is 0 to ensure that we never have negative population densities.

S1.2 The infinite population limit

We can now more clearly speak about what we mean by the infinite population limit. Recall that K is a population size measure (Czuppon and Traulsen, 2021). Since the growth rate is expected to be negative when $\sum_i n_i > K$, if a population is initiated with $\sum_i n_i(0)$ being $\mathcal{O}(K)$, the total population size $\sum_i n_i(t)$ does not have unbounded growth, but instead remains $\mathcal{O}(K)$ before the population eventually goes extinct. Thus, in terms of population densities $\mathbf{x}(t)$, the scaled population size $\sum_i x_i(t)$ remains $\mathcal{O}(1)$. When we speak of the ‘infinite population limit’ $K \rightarrow \infty$, we thus take the limit of $K \rightarrow \infty$ along with initial population size $\sum_i n_i(0) \rightarrow \infty$ such that the initial total scaled population size $\sum_i x_i(0)$ remains $\mathcal{O}(1)$. Thus, the limit in question is the standard domain of deterministic population models, namely, a model of a population with infinite population size but finite population density. Note that in the infinite population limit, we cannot speak of \mathbf{n} or K individually but only of the ratio $\mathbf{x} = \mathbf{n}/K$, which is guaranteed to remain well-defined by our scaling assumptions. A more thorough, rigorous treatment of the mathematical details behind the rescaling procedure and infinite population limit is presented in Champagnat et al., 2006.

S1.3 Step operators and system size expansion

To describe our stochastic process in terms of population densities rather than absolute population sizes, we now define new step operators Δ_i^\pm by their action on any real-valued function $f(\mathbf{x}, t)$ as

$$\Delta_i^\pm f([x_1, \dots, x_m], t) = f([x_1, \dots, x_i \pm \frac{1}{K}, \dots, x_m], t) \quad (\text{S5})$$

In terms of these new variables, (S2) becomes

$$\frac{\partial P}{\partial t}(\mathbf{x}, t) = K \sum_{j=1}^m \left[(\Delta_j^- - 1)b_j^{(K)}(\mathbf{x})P(\mathbf{x}, t) + (\Delta_j^+ - 1)d_j^{(K)}(\mathbf{x})P(\mathbf{x}, t) \right] \quad (\text{S6})$$

If K is large, we can now Taylor expand the action of the step operators as

$$f([x_1, \dots, x_i \pm \frac{1}{K}, \dots, x_m], t) = f(\mathbf{x}, t) \pm \frac{1}{K} \frac{\partial f}{\partial x_i}(\mathbf{x}, t) + \frac{1}{2K^2} \frac{\partial^2 f}{\partial x_i^2}(\mathbf{x}, t) + \dots$$

which, after substituting into (S6) and neglecting higher order terms, yields the equation

$$\frac{\partial P}{\partial t}(\mathbf{x}, t) = \sum_{j=1}^m \left[-\frac{\partial}{\partial x_j} \{A_j^-(\mathbf{x})P(\mathbf{x}, t)\} + \frac{1}{2K} \frac{\partial^2}{\partial x_j^2} \{A_j^+(\mathbf{x})P(\mathbf{x}, t)\} \right] \quad (\text{S7})$$

where

$$A_i^\pm(\mathbf{x}) = b_i^{(K)}(\mathbf{x}) \pm d_i^{(K)}(\mathbf{x})$$

Equation (S7) is an m -dimensional version of a ‘Fokker-Planck equation’ or ‘diffusion equation’ for the probability density $P(\mathbf{x}, t)$. For a more detailed discussion on ‘system size approximations’ such as the one we carried out above, we refer the reader to Chapter 11 of Ethier and Kurtz, 1986 for the mathematically rigorous theory and Chapter 10 of Van Kampen, 1981 for a heuristic approach. Pedagogical treatments focused on eco-evolutionary population dynamics can be found in Black and McKane, 2012 and Czuppon and Traulsen, 2021.

Itô SDE representation

For our purposes, we will often find it convenient to describe the same process as defined by the Fokker-Planck equation (S7) via an ‘Itô stochastic differential equation’. It is well-known (Øksendal, 1998) that a stochastic process whose probability density function satisfies a Fokker-Planck equation of the form (S7) is equivalent to an m -dimensional stochastic process obtained as the solution to the Itô SDE

$$d\mathbf{X}_t = \mathbf{A}^-(\mathbf{X}_t)dt + \frac{1}{\sqrt{K}}\mathbf{D}(\mathbf{X}_t)d\mathbf{W}_t \quad (\text{S8})$$

Here, $\mathbf{A}^-(\mathbf{X}_t)$ is an m -dimensional vector with i^{th} element $= A_i^-(\mathbf{X}_t)$. $\mathbf{D}(\mathbf{X}_t)$ is an $m \times m$ matrix with ij^{th} element $(\mathbf{D}(\mathbf{X}_t))_{ij} = \delta_{ij} (A_i^+ A_j^+)^{\frac{1}{4}}$, where δ_{ij} is the Kronecker delta symbol, defined by

$$\delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}$$

Finally, \mathbf{W}_t is the m -dimensional Wiener process (standard Brownian motion) and can be thought of as a vector of independent one-dimensional Wiener processes.

S2 Trait frequency dynamics using Itô’s formula

We first recall the version of the multi-dimensional Itô’s formula that will be relevant to us. Consider an m -dimensional real Itô process \mathbf{X}_t given by the solution to

$$d\mathbf{X}_t = \boldsymbol{\mu}(\mathbf{X}_t)dt + \boldsymbol{\sigma}(\mathbf{X}_t)d\mathbf{W}_t$$

where $\boldsymbol{\mu} : \mathbb{R}^m \rightarrow \mathbb{R}^m$ is the ‘drift vector’ and $\boldsymbol{\sigma} : \mathbb{R}^m \rightarrow \mathbb{R}^{m \times m}$ is the ‘diffusion matrix’. Let $f : \mathbb{R}^m \rightarrow \mathbb{R}$ be an arbitrary $C^2(\mathbb{R}^m)$ function. Then, Itô’s formula (Øksendal, 1998, Section 4.2) states that the stochastic process $f(\mathbf{X}_t)$ must satisfy:

$$df(\mathbf{X}_t) = \left[(\nabla_{\mathbf{x}} f)^T \boldsymbol{\mu} + \frac{1}{2} \text{Tr}[\boldsymbol{\sigma}^T (H_{\mathbf{x}} f) \boldsymbol{\sigma}] \right] dt + (\nabla_{\mathbf{x}} f)^T \boldsymbol{\sigma} d\mathbf{W}_t \quad (\text{S9})$$

where $\text{Tr}[\cdot]$ denotes the trace of a matrix, $(\cdot)^T$ denotes the transpose, and we have suppressed the \mathbf{X}_t dependence of $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ to reduce clutter. Here, $\nabla_{\mathbf{x}} f$ is the m -dimensional *gradient vector* of f with respect to \mathbf{x} and $H_{\mathbf{x}} f$ is the $m \times m$ *Hessian matrix* of f with respect to \mathbf{x} , respectively defined for $f([x_1, \dots, x_m]^T)$ as:

$$\begin{aligned} (\nabla_{\mathbf{x}} f)_j &= \frac{\partial f}{\partial x_j} \\ (H_{\mathbf{x}} f)_{jk} &= \frac{\partial^2 f}{\partial x_j \partial x_k} \end{aligned}$$

In our case, we have the Itô process given by (S8), which defines how the density of each type of individual changes over time. We thus have $\boldsymbol{\mu}(\mathbf{X}_t) = \mathbf{A}^-(\mathbf{X}_t)$ and $\boldsymbol{\sigma}(\mathbf{X}_t) = \mathbf{D}(\mathbf{X}_t)/\sqrt{K}$. For each fixed $i \in \{1, 2, \dots, m\}$, let us define a scalar function $f_i : \mathbb{R}^m \rightarrow \mathbb{R}$ as

$$f_i(\mathbf{x}) = \frac{x_i}{\sum_{j=1}^m x_j}$$

Thus, $f_i(\mathbf{X}_t)$ gives us the frequency of type i individuals when the population is described by the vector \mathbf{X}_t . As an aside, note that we only need to calculate frequencies for $i \in \{1, 2, \dots, m-1\}$ along with $N_K = \sum x_i$. We can now use Itô's formula (S9) to describe how f_i changes over time. The j^{th} element of the gradient of f_i is given by:

$$\begin{aligned}
 (\nabla_{\mathbf{x}} f_i)_j &= \frac{\partial}{\partial x_j} \left(\frac{x_i}{\sum_{k=1}^m x_k} \right) \\
 &= \left(\left(\frac{1}{\sum_{r=1}^m x_r} \right) \frac{\partial x_i}{\partial x_j} - \left(\frac{x_i}{\left(\sum_{r=1}^m x_r \right)^2} \right) \sum_{k=1}^m \frac{\partial x_k}{\partial x_j} \right)
 \end{aligned} \tag{S10}$$

where we have defined the frequency of the i^{th} type $p_i = f_i(\mathbf{x})$. To proceed further, we require the quantity $\frac{\partial x_j}{\partial x_k}$ for any pair of types $j, k \in \{1, 2, 3, \dots, m-1, m\}$. Since changes in densities in our system are only being determined by ecological interactions at the individual level, with changes in total population size being an emergent quantity, we can assume that our system obeys $\frac{\partial x_j}{\partial x_k} = \delta_{jk} \forall j, k \in \{1, 2, 3, \dots, m-1, m\}$. Note that this is *not* true if the total population size is held constant since changes in densities of one type must be accompanied by complementary changes in densities of at least one other type to keep the total density $\sum_i x_i$ strictly constant.

We can now substitute $\frac{\partial x_j}{\partial x_k} = \delta_{jk}$ into equation (S10). Upon doing this, we obtain

$$(\nabla_{\mathbf{x}} f_i)_j = \frac{1}{\sum_{r=1}^m x_r} (\delta_{ij} - p_i) \tag{S11}$$

Similarly, we can also calculate the Hessian. The jk^{th} element of the Hessian is given by:

$$\begin{aligned}
 (H_{\mathbf{x}} f_i)_{jk} &= \frac{\partial^2}{\partial x_j \partial x_k} \left(\frac{x_i}{\sum_{l=1}^m x_l} \right) \\
 &= \frac{\partial}{\partial x_j} \left(\frac{\delta_{ik}}{\sum_{r=1}^m x_r} - \frac{x_i}{\left(\sum_{r=1}^m x_r \right)^2} \right) \\
 &= \frac{1}{\left(\sum_{r=1}^m x_r \right)^2} (2p_i - \delta_{ij} - \delta_{ik})
 \end{aligned} \tag{S12}$$

Thus, for the first term of (S9), we have:

$$\begin{aligned}
 (\nabla_{\mathbf{x}} f_i)^T \mathbf{A}^- &= \sum_{j=1}^m ((\nabla_{\mathbf{x}} f_i)_j) A_j^- \\
 &= \frac{1}{\sum_{r=1}^m x_r} \sum_{j=1}^m (\delta_{ij} - p_i) A_j^- \\
 &= \frac{1}{\sum_{r=1}^m x_r} \left(A_i^- - p_i \sum_{j=1}^m A_j^- \right)
 \end{aligned} \tag{S13}$$

This term describes the effects of selection and influx (mutation/migration) at the infinite population limit. However, the finiteness of the population adds a second directional term to these dynamics, described by the second term that multiplies dt in (S9). To calculate it, we first calculate:

$$\begin{aligned} \frac{1}{\sqrt{K}} (H_{\mathbf{x}} f_i \mathbf{D})_{jk} &= \frac{1}{\sqrt{K}} \sum_{l=1}^m (H_{\mathbf{x}} f_i)_{jl} (\mathbf{D})_{lk} \\ &= \frac{1}{\sqrt{K} \left(\sum_{r=1}^m x_r \right)^2} \sum_{l=1}^m (2p_i - \delta_{ij} - \delta_{il}) \delta_{lk} (A_l^+ A_k^+)^{\frac{1}{4}} \end{aligned} \quad (\text{S14})$$

$$= \frac{1}{\sqrt{K} \left(\sum_{r=1}^m x_r \right)^2} \left((2p_i - \delta_{ij}) (A_k^+)^{\frac{1}{2}} - \delta_{ik} (A_i^+ A_k^+)^{\frac{1}{4}} \right) \quad (\text{S15})$$

$$= \frac{1}{\sqrt{K} \left(\sum_{r=1}^m x_r \right)^2} (2p_i - \delta_{ij} - \delta_{ik}) (A_k^+)^{\frac{1}{2}} \quad (\text{S16})$$

and thus:

$$\begin{aligned} \frac{1}{K} \left(\mathbf{D}^T H_{\mathbf{x}} f_i \mathbf{D} \right)_{lk} &= \frac{1}{K} \sum_{j=1}^m \left(\mathbf{D}^T \right)_{lj} (H_{\mathbf{x}} f_i \mathbf{D})_{jk} \\ &= \frac{1}{K \left(\sum_{r=1}^m x_r \right)^2} \sum_{j=1}^m \delta_{lj} (A_l^+ A_j^+)^{\frac{1}{4}} (A_k^+)^{\frac{1}{2}} (2p_i - \delta_{ij} - \delta_{ik}) \end{aligned} \quad (\text{S17})$$

$$= \frac{1}{K \left(\sum_{r=1}^m x_r \right)^2} (A_k^+)^{\frac{1}{2}} \left(2p_i (A_l^+)^{\frac{1}{2}} - (A_i^+)^{\frac{1}{2}} \delta_{il} - (A_l^+)^{\frac{1}{2}} \delta_{ik} \right) \quad (\text{S18})$$

Using this, we see that the trace of this matrix is given by:

$$\begin{aligned} \frac{1}{K} \text{Tr}[\mathbf{D}^T H_{\mathbf{x}} f_i \mathbf{D}] &= \frac{1}{K} \sum_{k=1}^m \left(\mathbf{D}^T H_{\mathbf{x}} f_i \mathbf{D} \right)_{kk} \\ &= \frac{1}{K \left(\sum_{r=1}^m x_r \right)^2} \sum_{k=1}^m \left(2p_i (A_k^+ A_k^+)^{\frac{1}{2}} - (A_i^+ A_k^+)^{\frac{1}{2}} \delta_{ik} - (A_k^+ A_k^+)^{\frac{1}{2}} \delta_{ik} \right) \end{aligned} \quad (\text{S19})$$

$$= \frac{1}{K \left(\sum_{r=1}^m x_r \right)^2} \left(2p_i \left(\sum_{k=1}^m A_k^+ \right) - 2A_i^+ \right) \quad (\text{S20})$$

and thus, the second term multiplying dt in (S9) is given by:

$$\frac{1}{2K} \text{Tr}[\mathbf{D}^T H_{\mathbf{x}} f_i \mathbf{D}] = \frac{-1}{K \left(\sum_{r=1}^m x_r \right)^2} \left(A_i^+ - p_i \left(\sum_{k=1}^m A_k^+ \right) \right) \quad (\text{S21})$$

Finally, denoting $d\mathbf{W}_t = [dW_t^{(1)}, dW_t^{(2)}, \dots, dW_t^{(m)}]^T$ where each $W_t^{(j)}$ is an independent one dimensional Wiener process, we have:

$$\begin{aligned} (\mathbf{D}d\mathbf{W}_t)_j &= \sum_{k=1}^m \mathbf{D}_{jk} dW_t^{(k)} \\ &= \sum_{k=1}^m \delta_{jk} \left(A_j^+ A_k^+ \right)^{\frac{1}{4}} dW_t^{(k)} \end{aligned} \quad (\text{S22})$$

$$= \left(A_j^+ \right)^{1/2} dW_t^{(j)} \quad (\text{S23})$$

Thus, using (S11), we see that the last term on the RHS of (S9) is given by:

$$\begin{aligned} \frac{1}{\sqrt{K}} (\nabla_{\mathbf{x}} f)^T \mathbf{D} d\mathbf{W}_t &= \frac{1}{\sqrt{K}} \sum_{j=1}^m (\nabla_{\mathbf{x}} f_i)_j (\mathbf{D} d\mathbf{W}_t)_j \\ &= \frac{1}{\left(\sum_{r=1}^m x_r \right) \sqrt{K}} \sum_{j=1}^m (\delta_{ij} - p_i) \left(A_j^+ \right)^{1/2} dW_t^{(j)} \end{aligned} \quad (\text{S24})$$

$$= \frac{1}{\left(\sum_{r=1}^m x_r \right) \sqrt{K}} \left(A_i^+ \right)^{1/2} dW_t^{(i)} - p_i \sum_{j=1}^m \left(A_j^+ \right)^{1/2} dW_t^{(j)} \quad (\text{S25})$$

Putting equations (S13), (S21) and (S25) into (S9) and letting $N_K(t) = \sum_{r=1}^m x_r$ we see that $p_i = f_i(\mathbf{X})_t$, the frequency of the i^{th} type in the population \mathbf{X}_t , changes according to the equation:

$$\begin{aligned}
 dp_i = & \underbrace{\frac{1}{N_K(t)} \left(A_i^- - p_i \sum_{j=1}^m A_j^- \right) dt}_{K \rightarrow \infty \text{ prediction}} - \underbrace{\frac{1}{K} \frac{1}{N_K^2(t)} \left(A_i^+ - p_i \left(\sum_{k=1}^m A_k^+ \right) \right) dt}_{\substack{\text{Directional finite size effects} \\ \text{due to differential turnover rates}}} \\
 & + \underbrace{\frac{1}{\sqrt{KN_K(t)}} \left[(A_i^+)^{1/2} dW_t^{(i)} - p_i \sum_{j=1}^m (A_j^+)^{1/2} dW_t^{(j)} \right]}_{\substack{\text{Non-directional finite size effects} \\ \text{due to stochastic fluctuations}}}
 \end{aligned} \tag{S26}$$

Plugging the functional forms of (S4) and the definitions of w_i and τ_i into the definitions of A_i^- and A_i^+ , we obtain the relations

$$\begin{aligned}
 A_i^- &= x_i w_i(\mathbf{x}) + \lambda Q_i(\mathbf{x}) \\
 A_i^+ &= x_i \tau_i(\mathbf{x}) + \lambda Q_i(\mathbf{x})
 \end{aligned} \tag{S27}$$

Thus, for the first term of (S26), we have

$$\begin{aligned}
 \frac{1}{N_K(t)} \left(A_i^- - p_i \sum_{j=1}^m A_j^- \right) &= \frac{1}{N_K(t)} [w_i(\mathbf{x})x_i + \lambda Q_i(\mathbf{x})] - \frac{p_i}{N_K(t)} \sum_{j=1}^m [w_j(\mathbf{x})x_j + \lambda Q_j(\mathbf{x})] \\
 &= w_i(\mathbf{x})p_i + \frac{\lambda}{N_K(t)} Q_i(\mathbf{x}) - p_i \sum_{j=1}^m \left[w_j(\mathbf{x})p_j + \frac{\lambda}{N_K(t)} Q_j(\mathbf{x}) \right]
 \end{aligned}$$

where we have used the definition of p_i from (iii). Now using the definition of mean fitness from (iv) and rearranging terms gives us

$$\frac{1}{N_K(t)} \left(A_i^- - p_i \sum_{j=1}^m A_j^- \right) = (w_i(\mathbf{x}) - \bar{w})p_i + \lambda \left[Q_i(\mathbf{p}) - p_i \left(\sum_{j=1}^m Q_j(\mathbf{p}) \right) \right] \tag{S28}$$

where we have defined $Q_j(\mathbf{p}) = Q_j(\mathbf{x})/N_K(t)$. Repeating the exact same calculations for the A_i^+ terms in the second term of (S26) now yields equation

$$\begin{aligned}
 dp_i(t) = & \underbrace{(w_i(\mathbf{x}) - \bar{w}) p_i dt}_{\substack{\text{Natural selection} \\ (w > \bar{w} \text{ preferred})}} + \underbrace{\frac{1}{KN_K(t)} (\tau_i(\mathbf{x}) - \bar{\tau}) p_i dt}_{\substack{\text{Noise-induced selection} \\ (\tau < \bar{\tau} \text{ preferred})}} \\
 & + \underbrace{\lambda \left(1 - \frac{1}{KN_K(t)}\right) \left[Q_i(\mathbf{p}) - p_i \left(\sum_{j=1}^m Q_j(\mathbf{p}) \right) \right] dt}_{\substack{\text{Effect of population influx terms} \\ (\text{not strongly affected by demographic stochasticity})}} \\
 & + \underbrace{\frac{1}{\sqrt{KN_K(t)}} \left[\sqrt{A_i^+(\mathbf{x})} dW_t^{(i)} - p_i \sum_{j=1}^m \sqrt{A_j^+(\mathbf{x})} dW_t^{(j)} \right]}_{\substack{\text{Non-directional noise-induced effects} \\ \text{due to stochastic fluctuations}}}
 \end{aligned} \tag{S29}$$

which is the first key result (5) presented in the main text upon setting $\lambda = 0$.

The third term on the RHS of Eq. S29 represents potential biasing effects due to the influx of individuals of type i in a manner that does not depend purely multiplicatively on the current population density x_i of type i individuals (for example, through immigration from an external population or mutation of other types during birth). Since $1 - 1/KN_K$ is typically very close to 1 for medium to large population size (KN_K), we see that such influxes of individuals are not strongly affected by demographic stochasticity and thus have qualitatively similar effects in small, large, and infinite populations. This observation justifies our decision to neglect such terms in the main text for the sake of conceptual clarity, keeping the goals of a synthesis in mind.

S3 A stochastic analog of the Price equation for finite, fluctuating populations

In this section, we will derive an SDE for the rate of change of the population mean value of any type-level quantity in finite, fluctuating populations. Let f be any type-level quantity, with value $f_i(t)$ for the i^{th} type. Using the product rule of calculus on the definition (iv) of the statistical mean tells us that we have the relation

$$\frac{d\bar{f}}{dt} = \frac{d}{dt} \left(\sum_{i=1}^m f_i p_i \right) = \sum_{i=1}^m \left(f_i \frac{\partial p_i}{\partial t} + p_i \frac{\partial f_i}{\partial t} \right) = \sum_{i=1}^m f_i \frac{\partial p_i}{\partial t} + \overline{\left(\frac{\partial f}{\partial t} \right)} \quad (\text{S30})$$

i.e.

$$d\bar{f} = \sum_{i=1}^m f_i dp_i + \overline{\left(\frac{\partial f}{\partial t} \right)} dt \quad (\text{S31})$$

We will further simplify the first term on the RHS of (S31). We do this by using (S29), which gives us a representation of dp_i . Using the RHS of (S29), we can conclude that we must have

$$\begin{aligned} \sum_{i=1}^m f_i dp_i &= \left(\sum_{i=1}^m f_i w_i(\mathbf{x}) p_i - \bar{w} \sum_{i=1}^m f_i p_i + \lambda \left[\sum_{i=1}^m Q_i(\mathbf{p}) f_i - \left(\sum_{j=1}^m Q_j(\mathbf{p}) \sum_{i=1}^m p_i f_i \right) \right] \right) dt \\ &\quad - \frac{1}{KN_K} \left(\sum_{i=1}^m f_i \tau_i(\mathbf{x}) p_i - \bar{\tau} \sum_{i=1}^m f_i p_i + \lambda \left[\sum_{i=1}^m Q_i(\mathbf{p}) f_i - \left(\sum_{j=1}^m Q_j(\mathbf{p}) \sum_{i=1}^m p_i f_i \right) \right] \right) dt \quad (\text{S32}) \\ &\quad \frac{1}{\sqrt{KN_K}} \left(\left[\sum_{i=1}^m f_i \sqrt{A_i^+(\mathbf{x})} dW_t^{(i)} - \sum_{i=1}^m f_i p_i \sum_{j=1}^m \sqrt{A_j^+(\mathbf{x})} dW_t^{(j)} \right] \right) \end{aligned}$$

now using the definition of the statistical mean from (iv) in equation (S32), we obtain

$$\begin{aligned} \sum_{i=1}^m f_i dp_i &= \left(\bar{fw} - \bar{f}\bar{w} + \lambda \left[\sum_{i=1}^m Q_i(\mathbf{p}) f_i - \left(\sum_{j=1}^m Q_j(\mathbf{p}) \bar{f} \right) \right] \right) dt \\ &\quad - \frac{1}{KN_K} \left(\bar{f\tau} - \bar{f}\bar{\tau} + \lambda \left[\sum_{i=1}^m Q_i(\mathbf{p}) f_i - \left(\sum_{j=1}^m Q_j(\mathbf{p}) \bar{f} \right) \right] \right) dt \quad (\text{S33}) \\ &\quad \frac{1}{\sqrt{KN_K}} \left(\left[\sum_{i=1}^m f_i \sqrt{A_i^+(\mathbf{x})} dW_t^{(i)} - \sum_{j=1}^m \bar{f} \sqrt{A_j^+(\mathbf{x})} dW_t^{(j)} \right] \right) \end{aligned}$$

By the definition of the statistical covariance (v), we now obtain

$$\begin{aligned}
 \sum_{i=1}^m f_i dp_i &= \text{Cov}(w, f) dt + \lambda \left[\sum_{i=1}^m Q_i(\mathbf{p}) f_i - \bar{f} \left(\sum_{j=1}^m Q_j(\mathbf{p}) \right) \right] dt \\
 &\quad - \frac{1}{KN_K} \left(\text{Cov}(w, f) dt + \lambda \left[\sum_{i=1}^m Q_i(\mathbf{p}) f_i - \bar{f} \left(\sum_{j=1}^m Q_j(\mathbf{p}) \right) \right] dt \right) \\
 &\quad \frac{1}{\sqrt{KN_K}} \left(\sum_{i=1}^m (f_i - \bar{f}) \sqrt{A_i^+(\mathbf{x})} dW_t^{(i)} \right)
 \end{aligned} \tag{S34}$$

Collecting all terms that capture effects related to mutations/migrations (*i.e.* all terms with a λ factor) via defining the term

$$M_{\bar{f}}(\mathbf{p}, N_K) := \lambda \left(1 - \frac{1}{KN_K(t)} \right) \left(\sum_{i=1}^m (f_i - \bar{f}) Q_i(\mathbf{p}) \right) \tag{S35}$$

and collecting all stochastic integral terms via defining the term

$$dW_{\bar{f}} := \sum_{i=1}^m (f_i - \bar{f}) \sqrt{A_i^+(\mathbf{x})} dW_t^{(i)} \tag{S36}$$

and substituting into equation (S34) now yields

$$\sum_{i=1}^m f_i dp_i = \text{Cov}(w, f) dt - \frac{1}{KN_K(t)} \text{Cov}(\tau, f) dt + M_{\bar{f}}(\mathbf{p}, N_K) dt + \frac{1}{\sqrt{KN_K(t)}} dW_{\bar{f}} \tag{S37}$$

This is the simplified version of the first term on the RHS of equation (S31). Upon substitution, (S31) becomes

$$d\bar{f} = \text{Cov}(w, f) dt - \frac{1}{KN_K(t)} \text{Cov}(\tau, f) dt + M_{\bar{f}}(\mathbf{p}, N_K) dt + \frac{1}{\sqrt{KN_K(t)}} dW_{\bar{f}} + \overline{\left(\frac{\partial f}{\partial t} \right)} dt \tag{S38}$$

which is precisely equation (12) in the main text once we set $\lambda = 0$ (*i.e.* $M_{\bar{f}} = 0$).

S4 A Price-like equation for the variance of a type-level quantity

In this section, we will derive an SDE for the rate of change of the variance of any type-level quantity in finite, fluctuating populations. From the definition (v), we see that the variance of any type level quantity f is given by:

$$\sigma_f^2 := \text{Cov}(f, f) = \overline{(f^2)} - (\bar{f})^2 \quad (\text{S39})$$

By the product rule, we have

$$\frac{d\sigma_f^2}{dt} = 2f \overline{\frac{\partial f}{\partial t}} + \sum_{i=1}^m f_i^2 \frac{dp_i}{dt} - \frac{d}{dt}(\bar{f}^2) \quad (\text{S40})$$

i.e.

$$d\sigma_f^2 = 2 \left(f \overline{\frac{\partial f}{\partial t}} \right) + \sum_{i=1}^m f_i^2 dp_i - d(\bar{f}^2) \quad (\text{S41})$$

We will evaluate the RHS term by term. The first term is as simplified as can be without more information about f . For the second term, we can substitute dp_i from (S29) and then use the exact same steps we carried out in supplementary section S3 to derive equation (S38). Upon doing this, we obtain

$$\begin{aligned} \sum_{i=1}^m f_i^2 dp_i &= \text{Cov}(w, f^2) dt - \frac{1}{KN_K} \text{Cov}(\tau, f^2) dt \\ &\quad + \lambda \left(1 - \frac{1}{KN_K(t)} \right) \left(\sum_{i=1}^m f_i^2 Q_i(\mathbf{p}) - \overline{f^2} \sum_{i=1}^m Q_i(\mathbf{p}) \right) dt \\ &\quad + \frac{1}{\sqrt{KN_K(t)}} \left(\sum_{i=1}^m (f_i^2 - \overline{f^2}) \sqrt{A_i^+} dW_t^{(i)} \right) \end{aligned} \quad (\text{S42})$$

For the third term, we require Itô's formula. Here, the relevant version of Itô's formula is the one-dimensional version of (S9). Given a one-dimensional process $dX_t = S(X_t)dt + \sum_j D_j(X_t)dW_t^{(j)}$ with S, D_j being suitable real functions and each $W_t^{(j)}$ being an independent Wiener process, Itô's

formula says that given any $C^2(\mathbb{R})$ function $g(x)$, we have the relation:

$$dg(X_t) = \left(S(X_t)g'(X_t) + \frac{g''(X_t)}{2} \sum_j D_j^2(X_t) \right) dt + \sum_j D_j(X_t)g'(X_t)dW_t^{(j)} \quad (\text{S43})$$

In our case, we have a one-dimensional process for the mean value $d\bar{f}$ of the type level quantity, and the $C^2(\mathbb{R})$ function $g(x) = x^2$. Itô's formula thus says that the third term of (S41) is given by:

$$d(\bar{f}^2) = \left(2\bar{f}S(X_t) + \sum_j D_j^2(X_t) \right) dt + \sum_j 2\bar{f}D_j(X_t)dW_t^{(j)} \quad (\text{S44})$$

where the relevant functions S and D_j can be read off from (S38). Since the $dW_t^{(j)}$ terms are unwieldy, we will denote the contribution of all the $dW_t^{(j)}$ terms collectively by $dW_{\sigma_f^2}$ to reduce notational clutter and only explicitly calculate these terms at the end.

We can thus calculate

$$\begin{aligned} d(\bar{f}^2) &= 2\bar{f} \left[\text{Cov}(w, f)dt - \frac{1}{KN_K(t)} \text{Cov}(\tau, f)dt + M_{\bar{f}}(\mathbf{p}, N_K) + \overline{\left(\frac{\partial f}{\partial t} \right)} \right] dt \\ &\quad + \left(\frac{1}{KN_K^2(t)} \sum_i (f_i - \bar{f}) \sqrt{A_i^+(\mathbf{x})} \right) dt + dW_{\sigma_f^2} \end{aligned} \quad (\text{S45})$$

We now observe that the covariance operator is a bilinear form, *i.e.* given any three quantities X , Y and Z and any constant $a \neq 0$, we have the relations:

$$\text{Cov}(aX, Y) = a\text{Cov}(X, Y) = \text{Cov}(X, aY)$$

$$\text{Cov}(X, Y + Z) = \text{Cov}(X, Y) + \text{Cov}(X, Z)$$

Substituting equations (S42) and (S45) into equation (S41) and using this property of covariances for the $\text{Cov}(w, \cdot)$ and $\text{Cov}(\tau, \cdot)$ terms, we obtain:

$$\begin{aligned}
 d\sigma_f^2 &= \text{Cov}(w, f^2 - 2\bar{f}f)dt - \frac{1}{KN_K} \left(\text{Cov}(\tau, f^2 - 2\bar{f}f) \right) dt + 2 \left(\overline{f \frac{\partial f}{\partial t}} - \bar{f} \overline{\left(\frac{\partial f}{\partial t} \right)} \right) dt \\
 &\quad + \lambda \left(1 - \frac{1}{KN_K(t)} \right) \left(\sum_{i=1}^m (f_i^2 - 2\bar{f}f_i) Q_i(\mathbf{p}) - (\bar{f}^2 - 2\bar{f}^2) \sum_{i=1}^m Q_i(\mathbf{p}) \right) dt \\
 &\quad - \frac{1}{KN_K^2(t)} \left(\sum_{i=1}^m (f_i - \bar{f})^2 A_i^+ \right) dt \\
 &\quad + dW_{\sigma_f^2}
 \end{aligned} \tag{S46}$$

Now, we note that

$$\frac{1}{N_K} A_i^+ = \frac{1}{N_K} (\tau_i x_i + \lambda Q_i(\mathbf{x})) \tag{S47}$$

$$= \tau_i p_i + \lambda Q_i(\mathbf{p}) \tag{S48}$$

and thus the third line of (S46) is

$$\frac{1}{KN_K^2(t)} \left(\sum_{i=1}^m (f_i - \bar{f})^2 A_i^+ \right) dt = \frac{1}{KN_K} \sum_{i=1}^m (f_i - \bar{f})^2 (\tau_i p_i + \lambda Q_i(\mathbf{p})) \tag{S49}$$

$$= \frac{1}{KN_K} \sum_{i=1}^m (f_i - \bar{f})^2 (\tau_i p_i + \lambda Q_i(\mathbf{p})) \tag{S50}$$

$$= \frac{1}{KN_K} \left(\overline{\left(f - \bar{f} \right)^2} + \lambda \sum_{i=1}^m (f_i - \bar{f})^2 Q_i(\mathbf{p}) \right) \tag{S51}$$

$$\begin{aligned}
 &= \frac{1}{KN_K} \left(\text{Cov}(\tau, (f - \bar{f})^2) + \bar{\tau} \overline{(f - \bar{f})^2} + \lambda \sum_{i=1}^m (f_i - \bar{f})^2 Q_i(\mathbf{p}) \right) \\
 &\quad (S52)
 \end{aligned}$$

$$= \frac{1}{KN_K} \left(\text{Cov}(\tau, (f - \bar{f})^2) + \bar{\tau} \sigma_f^2 + \lambda \sum_{i=1}^m (f_i - \bar{f})^2 Q_i(\mathbf{p}) \right) \tag{S53}$$

where we have used the definition of statistical covariance in the second to last line and used the definition of statistical variance in the last line. Substituting (S53) into (S46) and using $M_{\sigma_f^2}(\mathbf{p}, N_K)$

to denote the contributions of all the mutational terms (*i.e.* all terms with a λ factor) for notational brevity, we obtain

$$\begin{aligned} d\sigma_f^2 &= \text{Cov}(w, f^2 - 2\bar{f}f)dt - \frac{1}{KN_K} \left(\text{Cov}(\tau, f^2 - 2\bar{f}f) + \text{Cov}(\tau, (f - \bar{f})^2) + \bar{\tau}\sigma_f^2 \right) dt \\ &\quad + 2\text{Cov}\left(\frac{\partial f}{\partial t}, f\right) dt + M_{\sigma_f^2}(\mathbf{p}, N_K)dt + dW_{\sigma_f^2} \end{aligned} \quad (\text{S54})$$

We can now complete the square inside the covariance terms of the first line of the RHS by writing $f^2 - 2\bar{f}f = (f - \bar{f})^2 - \bar{f}^2$ to obtain

$$\begin{aligned} d\sigma_f^2 &= \left[\text{Cov}\left(w, (f - \bar{f})^2\right) - \text{Cov}\left(w, (\bar{f})^2\right) \right] dt \\ &\quad - \frac{1}{KN_K} \left[\text{Cov}\left(\tau, (f - \bar{f})^2\right) - \text{Cov}\left(\tau, (\bar{f})^2\right) + \text{Cov}(\tau, (f - \bar{f})^2) + \bar{\tau}\sigma_f^2 \right] dt \\ &\quad + 2\text{Cov}\left(\frac{\partial f}{\partial t}, f\right) dt + M_{\sigma_f^2}(\mathbf{p}, N_K)dt + dW_{\sigma_f^2} \end{aligned} \quad (\text{S55})$$

To simplify the covariance terms of the first line of the RHS, we observe that

$$\begin{aligned} \text{Cov}\left(w, (\bar{f})^2\right) &= \overline{\left(w(\bar{f})^2\right)} - \bar{w}\overline{(\bar{f})^2} \\ &= (\bar{f})^2 \sum_{i=1}^m w_i p_i - \bar{w}(\bar{f})^2 \sum_{i=1}^m p_i \\ &= (\bar{f})^2 \bar{w} - \bar{w}(\bar{f})^2 = 0 \end{aligned}$$

and similarly,

$$\text{Cov}\left(\tau, (\bar{f})^2\right) = 0$$

and thus, using this in (S55), we see that the rate of change of the variance of any type-level quantity f in the population satisfies:

$$d\sigma_f^2 = \text{Cov} \left(w, (f - \bar{f})^2 \right) dt - \frac{1}{KN_K} \left[\bar{\tau}\sigma_f^2 + 2\text{Cov} \left(\tau, (f - \bar{f})^2 \right) \right] dt \\ + 2\text{Cov} \left(\frac{\partial f}{\partial t}, f \right) dt + M_{\sigma_f^2}(\mathbf{p}, N_K) dt + dW_{\sigma_f^2} \quad (\text{S56})$$

This is precisely equation (17) in the main text. To calculate the mutation term, we substitute (S53) into (S46) to find

$$M_{\sigma_f^2}(\mathbf{p}, N_K) = \lambda \left(\sum_{i=1}^m \left(f_i^2 - 2\bar{f}f_i - \bar{f}^2 + 2\bar{f}^2 \right) Q_i(\mathbf{p}) \right) \\ - \frac{\lambda}{KN_K} \sum_{i=1}^m \left(f_i^2 - 2\bar{f}f_i - \bar{f}^2 + 2\bar{f}^2 + (f_i - \bar{f})^2 \right) Q_i(\mathbf{p}) \quad (\text{S57})$$

We can further simplify the first term of the RHS as

$$f_i^2 - 2\bar{f}f_i - \bar{f}^2 + 2\bar{f}^2 = (f_i^2 + \bar{f}^2 - 2\bar{f}f_i) - (\bar{f}^2 - \bar{f}^2) \\ = (f_i - \bar{f})^2 - \sigma_f^2$$

and similarly, the second term as

$$f_i^2 - 2\bar{f}f_i - \bar{f}^2 + 2\bar{f}^2 + (f_i - \bar{f})^2 = 2(f_i - \bar{f})^2 - \sigma_f^2$$

thus, the contributions of influx terms to the change in the variance of f are given by

$$M_{\sigma_f^2}(\mathbf{p}, N_K) = \lambda \left(\sum_{i=1}^m \left((f_i - \bar{f})^2 - \sigma_f^2 \right) Q_i(\mathbf{p}) \right) \\ - \frac{\lambda}{KN_K} \sum_{i=1}^m \left(2(f_i - \bar{f})^2 - \sigma_f^2 \right) Q_i(\mathbf{p}) \quad (\text{S58})$$

which after slight rearrangement becomes

$$M_{\sigma_f^2}(\mathbf{p}, N_K) = \lambda \left(\sum_{i=1}^m \left[\left(1 - \frac{2}{KN_K}\right) (f_i - \bar{f})^2 Q_i(\mathbf{p}) \right] - \sigma_f^2 \left(1 - \frac{1}{KN_K}\right) \sum_{i=1}^m Q_i(\mathbf{p}) \right) \quad (\text{S59})$$

Finally, for the stochastic integral term, we can use equations (S42) and (S44) to calculate:

$$dW_{\sigma_f^2} = \frac{1}{\sqrt{KN_K(t)}} \left(\sum_{i=1}^m \left(f_i^2 - \bar{f}^2 - 2\bar{f}(f_i - \bar{f}) \right) \sqrt{A_i^+} dW_t^{(i)} \right) \quad (\text{S60})$$

$$= \frac{1}{\sqrt{KN_K(t)}} \left(\sum_{i=1}^m \left(f_i^2 - \bar{f}^2 - 2\bar{f}f_i - 2\bar{f}^2 \right) \sqrt{A_i^+} dW_t^{(i)} \right) \quad (\text{S61})$$

$$= \frac{1}{\sqrt{KN_K(t)}} \left(\sum_{i=1}^m \left(f_i - \bar{f} \right)^2 \sqrt{A_i^+} dW_t^{(i)} \right) \quad (\text{S62})$$

which is equation (18) in the main text upon setting $\lambda = 0$ (*i.e.* $M_{\sigma^2} = 0$).

S5 A more elegant representation of sums of stochastic integrals against independent Wiener processes

We have arrived at three stochastic differential equations (equations (S29), (S38), and (S60)) that describe the change in the frequency of a type, the population mean value of a type-level quantity, and the population variance of a type-level quantity over time. All three of these equations contain sums of stochastic integrals of several independent functions against independent Wiener processes. In this section, we will present a more elegant representation of these terms as a single stochastic integral.

Let us first recall that given m independent one-dimensional Wiener processes $W_t^{(1)}, W_t^{(2)}, \dots, W_t^{(m)}$, m ‘nice’ real functions $g_1(x), g_2(x), \dots, g_m(x)$, and the stochastic process

$$dX_t = \sum_{i=1}^m g_i(X_t) dW_t^{(i)}$$

We can always find a *single* one-dimensional Wiener process W_t such that

$$dX_t = \left(\sum_{i=1}^m g_i^2(X_t) \right)^{1/2} dW_t$$

This result is well-known but we were unable to find a reference that explicitly proved it, and so we prove it as a lemma at the end of this supplementary section.

Using this result, we can now calculate the stochastic integral terms of our equations. For equation (7), we can calculate

$$\sum_{i=1}^m (x_i \tau_i + \lambda Q_i(\mathbf{x})) dW_t^{(i)} = \left[\sum_{i=1}^m x_i \tau_i + \lambda \sum_{i=1}^m Q_i(\mathbf{x}) \right]^{1/2} dW_t^{N_K} \quad (\text{S63})$$

$$= \left[\bar{\tau} N_K(t) + \lambda \sum_{i=1}^m Q_i(\mathbf{x}) \right]^{1/2} dW_t^{N_K} \quad (\text{S64})$$

where $W_t^{N_K}$ is a one-dimensional Wiener process. For equation (S29), the stochastic analog of the replicator-mutator equation, we find that the noise term can be written as a stochastic integral against a single Wiener process W_t as

$$\frac{1}{\sqrt{K N_K(t)}} \left[p_i (1 - p_i)^2 \tau_i + p_i^2 \left(\sum_{j \neq i} \tau_j p_j \right) + \lambda \left\{ (1 - p_i)^2 Q_i(\mathbf{p}) + p_i^2 \sum_{j \neq i} Q_j(\mathbf{p}) \right\} \right]^{1/2} dW_t \quad (\text{S65})$$

Note that the inclusion of influx terms ($\lambda \neq 0$) in Eqs S65 means the stochastic fluctuations do *not* vanish at the boundaries of $[0, 1]^m$. Studying whether the resultant process is well-behaved (i.e. guaranteed to remain confined in $[0, 1]^m$ for all times $t > 0$) is beyond the scope of this work.

For equation (S38), the stochastic analog of the Price equation, we have:

$$dW_{\bar{f}} = \sum_{i=1}^m (f_i - \bar{f}) \sqrt{A_i^+(\mathbf{x})} dW_t^{(i)} = \left(\sum_{i=1}^m (f_i - \bar{f})^2 A_i^+(\mathbf{x}) \right)^{1/2} dW_t \quad (\text{S66})$$

where W_t is now a single one-dimensional Wiener process. This is precisely the term calculated in

equation (S53) (barring the $1/KN_K^2$ pre-factor), and thus the stochastic term for the mean value is given by:

$$dW_{\bar{f}} = \sqrt{N_K(t) \left(\text{Cov}(\tau, (f - \bar{f})^2) + \bar{\tau}\sigma_f^2 + \lambda \sum_{i=1}^m (f_i - \bar{f})^2 Q_i(\mathbf{p}) \right)} dW_t \quad (\text{S67})$$

Similarly, for the variance equation (S60), we can write

$$dW_{\sigma_f^2} = \sum_{i=1}^m (f_i - \bar{f})^2 \sqrt{A_i^+(\mathbf{x})} dW_t^{(i)} = \left(\sum_{i=1}^m (f_i - \bar{f})^4 A_i^+(\mathbf{x}) \right)^{1/2} dW_t \quad (\text{S68})$$

where W_t is now a single one-dimensional Wiener process. A calculation exactly analogous to that done in obtaining (S53) reveals that this term can be written as

$$dW_{\sigma_f^2} = \sqrt{N_K(t) \left(\text{Cov}(\tau, (f - \bar{f})^4) + \bar{\tau}(\sigma_f^2)^2 + \lambda \sum_{i=1}^m (f_i - \bar{f})^4 Q_i(\mathbf{p}) \right)} dW_t \quad (\text{S69})$$

which is the representation used in the main text (with $\lambda = 0$).

Proof of the representation of sums of stochastic integrals with respect to independent Wiener processes

Here, we prove the mathematical result we used above. We stress once again that this is not a new result — we provide the proof here because, while the proof is mathematically straightforward, we were unable to find a suitable citation that explicitly writes down the proof.

Lemma. Let $m \in \mathbb{N}$. Let $W_t^{(1)}, W_t^{(2)}, \dots, W_t^{(m)}$ be m independent one-dimensional Wiener processes. Let $g_1(x), g_2(x), \dots, g_m(x)$ be m ‘nice’ ($L^2(\mathbb{R})$, Lipschitz, etc.) real functions. Let

$$dX_t = \sum_{i=1}^m g_i(X_t) dW_t^{(i)}$$

Then, we can always find a *single* one-dimensional Wiener process W_t (on the same probability

space) such that

$$dX_t = \left(\sum_{i=1}^m g_i^2(X_t) \right)^{1/2} dW_t$$

Proof. It suffices to prove the $m = 2$ case.

Let $dX_t = g_1(X_t)dW_t^{(1)} + g_2(X_t)dW_t^{(2)}$. Let us consider the two-dimensional process $\mathbf{W}_t = [W_t^{(1)}, W_t^{(2)}]^\top$ on \mathbb{R}^2 . Define a new function $G : \mathbb{R} \rightarrow \mathbb{R}^2$ given by

$$G(x) = \frac{1}{\sqrt{g_1^2(x) + g_2^2(x)}} \begin{bmatrix} g_1(x) \\ g_2(x) \end{bmatrix} \quad (\text{S70})$$

Now, by definition, we have

$$\int_0^t G(X_s) \cdot d\mathbf{W}_s = \int_0^t \frac{g_1(X_s)}{\sqrt{g_1^2(X_s) + g_2^2(X_s)}} dW_s^{(1)} + \int_0^t \frac{g_2(X_s)}{\sqrt{g_1^2(X_s) + g_2^2(X_s)}} dW_s^{(2)} \quad (\text{S71})$$

Using the Itô isometry (Karatzas and Shreve, 1998, Chapter 2, Proposition 2.10), we can calculate the quadratic variation of $\int G \cdot d\mathbf{W}$ as

$$\begin{aligned} \left\langle \int G(X_s) \cdot d\mathbf{W}_s \right\rangle_t &= \int_0^t \|G(X_s)\|^2 d\langle \mathbf{W} \rangle_s \\ &= \int_0^t \frac{1}{g_1^2 + g_2^2} \cdot (g_1^2 + g_2^2) ds \\ &= \int_0^t ds = t \end{aligned} \quad (\text{S72})$$

Since $\int G \cdot d\mathbf{W}$ is a stochastic integral, the process $(t, \omega) \rightarrow \int_0^t G(X_s(\omega)) \cdot d\mathbf{W}_s(\omega) \in \mathcal{M}_2^c$ and is thus a continuous martingale. But, by Lévy's characterization of Brownian motion (Karatzas and Shreve, 1998, Chapter 3, Theorem 3.16), the only continuous martingale M_t that satisfies

$\langle M \rangle_t = t$ is the Wiener process. Thus, from equation (S72), we are led to conclude that there is a one-dimensional Wiener process W_t on the same probability space such that we can write

$$G(X_t) \cdot d\mathbf{W}_t = dW_t \quad (\text{S73})$$

We can now use equation (S71) on the LHS of equation (S73) to write

$$\frac{g_1(X_t)}{\sqrt{g_1^2(X_t) + g_2^2(X_t)}} dW_t^{(1)} + \frac{g_2(X_t)}{\sqrt{g_1^2(X_t) + g_2^2(X_t)}} dW_t^{(2)} = dW_t \quad (\text{S74})$$

$$\Rightarrow g_1 dW_t^{(1)} + g_2 dW_t^{(2)} = \sqrt{g_1^2(X_t) + g_2^2(X_t)} dW_t \quad (\text{S75})$$

By definition of our original process X_t , we can now conclude that

$$dX_t = \sqrt{g_1^2(X_t) + g_2^2(X_t)} dW_t \quad (\text{S76})$$

thus completing the proof. \square

S6 The speed density of the stochastic replicator equation for two species

To study the effects of demographic stochasticity on evolutionary dynamics more thoroughly, we use this section to examine the time that the system defined by equation (8) spends at different states. Following McLeod and Day, 2019, we will do this using the speed density. Given any one-dimensional diffusion process $dX_t = \mu(X_t)dt + \sigma(X_t)dW_t$ defined over an interval $[a, b] \subseteq \mathbb{R}$, the *speed density* $m(x)$ of the process (Karlin and Taylor, 1981; Etheridge, 2011) is defined as the function

$$m(x) = \frac{1}{\sigma^2(x)} \exp \left(2 \int_a^x \frac{\mu(y)}{\sigma^2(y)} dy \right) \quad (\text{S77})$$

where the lower limit of the integral being left unspecified is meant to denote an indefinite integral evaluated at the point x since the choice of the lower limit is arbitrary (Karlin and Taylor, 1981, Chapter 15, Equation 3.10). The speed density is important because it provides information about the long-term behavior of the stochastic process X_t . In particular, if there exists a constant $0 < \mathcal{N} < \infty$ such that $\int_a^b m(x)dx = 1/\mathcal{N}$, then the stochastic process obtained as the solution to $dX_t = \mu(X_t)dt + \sigma(X_t)dW_t$ attains a unique stationary state X_∞ as $t \rightarrow \infty$, and this stationary state has a probability distribution given by (Karlin and Taylor, 1981, Chapter 15, Equation 5.34 along with Chapter 15, Equation 3.10; also see Czuppon and Traulsen, 2021)

$$\mathbb{P}(\{x_1 \leq X_\infty \leq x_2\}) = \mathcal{N} \int_{x_1}^{x_2} m(x)dx + C \quad (\text{S78})$$

That is to say, the probability density of the stationary state will be given by $\mathcal{N}m(x)$. Regardless of whether such an \mathcal{N} can be found, the speed density $m(x)$ always tells us about the time the system spends in the vicinity of the point x . More precisely, if we provide an initial condition $x_0 \in [a, b]$ for the stochastic process obtained as the solution to $dX_t = \mu(X_t)dt + \sigma(X_t)dW_t$, the expected time taken by this process to exit the interval $(x_0 - \epsilon, x_0 + \epsilon)$ is proportional to $m(x_0)$ as $\epsilon \rightarrow 0$ (Karlin and Taylor, 1981, Chapter 15, Remark 3.2). This justified the name ‘speed density’. The quantity $M(p) = \int_p^b m(q)dq$ is called the speed measure. If a *quasi-stationary distribution* (Collet et al., 2013, definition 2.1) exists, the speed measure describes the quasi-stationary distribution (Collet et al., 2013, section 6.1.1) of the Markov process. A quasi-stationary distribution is known to exist under very general conditions for the kind of processes we study here (Champagnat and Villemonais, 2023).

In our case, we have a stochastic process for the change of type frequencies over time that takes values in $[0, 1]$ and is given by the solution to equation (9). In the rest of this section, we work

with equation (8a) and thus do not account for influx terms λQ_i . For convenience, let us define

$$E(p) = s(p, N_K) + \frac{1}{KN_K} \kappa(p, N_K) \quad (\text{S79})$$

$$V(p) = \frac{1}{KN_K} (\tau_1(p, N_K) + p\kappa(p, N_K)) \quad (\text{S80})$$

where we have suppressed the N_K dependence of E and V to reduce clutter. In this notation, equation (9) becomes

$$dp = p(1-p)E(p)dt + \sqrt{p(1-p)V(p)}dW_t \quad (\text{S81})$$

Comparing terms with (S77), we see that the speed density of our process is given by

$$m(p) = \frac{1}{p(1-p)V(p)} \exp \left(2 \int^p \frac{E(q)}{V(q)} dq \right) \quad (\text{S82})$$

For general functions $E(p)$ and $V(p)$, it is very often impossible to analytically calculate or predict the behavior of the complete function defined by (S82). However, since we are primarily interested in which trait frequencies p are likely, we can still make analytical progress by examining the derivative dm/dp . If dm/dp is a strictly increasing function of p , then higher values of frequency p are always favored, and species 2 is expected to go extinct more often than species 1. Likewise, if dm/dp is a strictly decreasing function of p , lower frequencies of p are favored, and species 1 is expected to go extinct. Lastly, points at which $dm/dp = 0$ correspond to extrema of the speed density and can thus be used to find the most likely and least likely values of trait frequency in the system.

We would therefore like to examine the behavior of dm/dp as a function of p . Differentiating both sides of equation (S82) with respect to p , we find

$$\frac{dm}{dp} = m(p) \left[\frac{2p-1}{p(1-p)} + 2 \frac{E(p)}{V(p)} - \frac{1}{V(p)} \frac{dV}{dp} \right] \quad (\text{S83})$$

which is Eq. 10 in the main text.

After substituting the functional form of $V(p)$ from equation (S80), this yields (after some lines of algebra):

$$\frac{dm}{dp} = m(p) \left[\frac{2p - 1}{p(1-p)} + 2\frac{E(p)}{V(p)} + \frac{1}{N_K} \frac{dN_K}{dp} - \frac{1}{V(p)} \left(\kappa(p, N_K) + (1-p) \frac{d\tau_1}{dp} + p \frac{d\tau_2}{dp} \right) \right] \quad (\text{S84})$$

Let us examine each term on the RHS of equation (S84). The first term on the RHS is $(2p - 1)/p(1-p)$. This expression is (anti)-symmetric about $p = 0.5$ and always drives the system towards the boundaries of $[0, 1]$. It is thus uninteresting for calculating the sign of dm/dp .

Since $V(p)$ must clearly be non-negative in order for equation (S81) to be well-defined, the second term, $E(p)/V(p)$, always has the same sign as $E(p)$. Equation (S84) tells us that the speed density (and thus the stationary distribution, when it exists) also depends on contributions from the dW_t term of equation (S81). We have split this contribution into two separate terms, the third and fourth terms on the RHS of equation (S84), each of which we will examine individually.

The third term on the RHS of (S84) captures the effect of the frequency of species 1 on the per-capita growth rate of the population as a whole. Thus, if species 1 is altruistic, mutualistic, or commensal, then dN_K/dp will be positive, whereas if the species is spiteful, competitive, or amensal, dN_K/dp will be negative. The sign of the third term on the RHS of (S84) thus depends on the nature of the ecological interactions that species 1 is involved in — species that increase the per-capita growth rate of the total population are favored, and those that decrease the per-capita growth rate of the total population are disfavored.

The fourth term on the RHS of equation (S84) captures the effects of noise-induced selection acting on differential turnover rates. Since $E(p)$ also has both a $1/V(p)$ factor and a noise-induced selection term, we are better off substituting the functional form of $E(p)$ from (S79) into equation (S84) and collecting all terms with a $1/V(p)$ factor so as to collect all terms corresponding to selection (both classical and noise-induced). Upon doing this, we obtain

$$\frac{dm}{dp} = m(p) \left[\frac{2p - 1}{p(1-p)} + \frac{1}{N_K} \frac{dN_K}{dp} + \frac{1}{V(p)} \left(2KN_K s(p, N_K) + \kappa(p, N_K) - (1-p) \frac{d\tau_1}{dp} - p \frac{d\tau_2}{dp} \right) \right] \quad (\text{S85})$$

The interpretations of the first two terms on the RHS of (S85) have already been explained above. Since $V(p)$ is always non-negative, we only need to look at the sign of the expression

$$2KN_K s(p, N_K) + \kappa(p, N_K) - (1-p) \frac{d\tau_1}{dp} - p \frac{d\tau_2}{dp} \quad (\text{S86})$$

The first term of (S86) is the effect of classical selection and has the same sign as the selection coefficient $s(p, N_K)$. Notice that since this term is $\mathcal{O}(K)$ whereas all other terms in equation (S85) are $\mathcal{O}(1)$, this term dominates the dynamics when K is large, again indicating that the effects of natural selection dominate in large populations with non-zero selection coefficient. If instead $Ks(p, N_K)$ is small, either through a small population size, weak selection (or no selection), or both, the last three terms of (S86) play a stronger role. The second term of (S86) is simply the noise-induced selection coefficient $\kappa(p)$, and is thus positive whenever $\tau_1 < \tau_2$. This term thus captures the direct mechanism of noise-induced biasing via noise-induced selection and causes the speed density to be biased towards the species with lower per-capita turnover rates. However, when the turnover rates depend on the frequency of traits, the last two terms of (S86) also affect the shape of the speed density. These two terms capture the *indirect* mechanism of noise-induced biasing via frequency-dependent turnover and bias the population towards those states which are associated with lower rates of change of the population as a whole. Note that the total strength of the effect of frequency dependence of a given type is inversely proportional to the current frequency of that type ($d\tau_1/dp$ is multiplied by $1 - p$ and $d\tau_2/dp$ is multiplied by p). This reflects the intuitive observation that stochastic effects on a focal type should play a stronger role when that type is rare.

S7 The infinite population limit recovers standard equations of population biology

In this section, we show how our SDEs recover several classic equations of population biology in the infinite population size limit.

Replicator-mutator equation

If we take $K \rightarrow \infty$ in (S29), we obtain an ODE that reads:

$$\frac{dp_i}{dt} = (w_i(\mathbf{x}) - \bar{w})p_i + \lambda \left[Q_i(\mathbf{p}) - p_i \left(\sum_{j=1}^m Q_j(\mathbf{p}) \right) \right] \quad (\text{S87})$$

The first term of (S87) describes changes due to faithful (non-mutational) replication, and the second describes changes due to mutation. For this reason, equation (S87) is called the *replicator-mutator equation* in the evolutionary game theory literature, where the individual ‘types’ are interpreted to be pure strategies and the influx rate λ is a mutation rate, denoted by μ . If in addition, each $w_i(\mathbf{x})$ is linear in \mathbf{x} , meaning we can write $w_i(\mathbf{x}) = \sum_j a_{ij}x_j$ for some set of constants a_{ij} , then we get the replicator-mutator equation for matrix games, and the constants a_{ij} form the ‘payoff matrix’. As is well-known, the replicator equation (without mutation) for matrix games with m pure strategies is equivalent to the generalized Lotka-Volterra equations for a community with $m-1$ species (Hofbauer and Sigmund, 1998), providing the connection to community ecology. Equation (S87) is also equivalent to Eigen’s *quasispecies equation* from molecular evolution if each ‘type’ is interpreted as a genetic sequence and each $w_i(\mathbf{x})$ is a constant function (Page and Nowak, 2002).

(Dynamical) Price equation

Taking $K \rightarrow \infty$ in equation (S38) recovers the Price equation as the infinite population limit. Here, we mean the Price equation as formulated in continuous time with time-varying characters (Lion, 2018; Day et al., 2020).

$$\frac{d\bar{f}}{dt} = \text{Cov}(w, f) + \overline{\left(\frac{\partial f}{\partial t} \right)} + \lambda \left(\sum_{i=1}^m f_i Q_i(\mathbf{p}) - \bar{f} \sum_{i=1}^m Q_i(\mathbf{p}) \right) \quad (\text{S88})$$

Many authors additionally assume that the quantity f does not itself change over time at the type level, meaning that $\partial f_i / \partial t \equiv 0 \forall i$ and the feedback term thus disappears. This yields a somewhat more familiar equation in continuous time (Lion, 2018). Standard texts also usually use a version formulated in discrete time that is more general for single-step changes, but is dynamically insufficient (Frank, 2012; Queller, 2017).

Fisher's fundamental theorem of natural selection

Taking $K \rightarrow \infty$ in (14) and noting that the process tends to a deterministic process as $K \rightarrow \infty$, as noted in section S7 (and thus the expectation value in the infinite population case is superfluous), we obtain an ODE:

$$\frac{d\bar{w}}{dt} = \sigma_w^2(t) + \overline{\left(\frac{\partial w}{\partial t} \right)} \quad (\text{S89})$$

This is Fisher's fundamental theorem in the presence of ecological feedbacks to fitness (Frank and Slatkin, 1992; Kokko, 2021).

The equation for trait variances that appears in Lion, 2018

Taking $K \rightarrow \infty$ in equation (S60) yields

$$\frac{d\sigma_f^2}{dt} = \text{Cov} \left(w, (f - \bar{f})^2 \right) + 2\text{Cov} \left(\frac{\partial f}{\partial t}, f \right) + \lambda \left[\left(\sum_{i=1}^m (f_i - \bar{f})^2 Q_i(\mathbf{p}) \right) + \sigma_f^2 \sum_{i=1}^m Q_i(\mathbf{p}) \right] \quad (\text{S90})$$

This is precisely equation (14) in Lion, 2018 with influx terms λQ_i .

S8 Noise-induced biasing in various specific contexts

In many social evolution models, cooperators are predicted to go extinct in infinite populations but are actually favored by evolution in finite, fluctuating populations, causing a ‘reversal’ in the direction of evolution predicted by natural selection (Houchmandzadeh and Vallade, 2012; Chotibut and Nelson, 2015; Constable et al., 2016; McLeod and Day, 2019). McLeod and Day, 2019 have recently shown that such reversals can occur in a wide array of social evolution models due to the same effect that we recognize here as noise-induced biasing. Formally, all the models presented in McLeod and Day, 2019 can be recovered in our framework by setting $m = 2$ and $s(\mathbf{x}) = -\epsilon c(\mathbf{x})$ for a constant $\epsilon \in \mathbb{R}$ and a non-negative function $c(\mathbf{x})$ in our stochastic replicator-mutator equation (Eq. S29). The function $T(p)$ in McLeod and Day, 2019 — a quantity that varies in the various models they study — is precisely the mean turnover $\bar{\tau}$ in our framework.

In evolutionary epidemiology, models have shown that reduced virulence is more important than increased transmission rate for pathogen spread in finite, fluctuating populations, especially when the population size is small (Humplik et al., 2014; Parsons et al., 2018; Day et al., 2020). Indeed, if the population is small or selection is weak, slower strains can have higher fixation probabilities than faster strains even if the slower strain has a lower basic reproduction ratio (R_0) than its competitor, causing a complete reversal in the direction of evolution predicted in infinite populations (Parsons et al., 2018). These results have recently been explained in a generic manner using both a replicator-mutator/‘stochastic adaptive dynamics’ approach (Parsons et al., 2018) and a two-species Price equation formalism (Day et al., 2020), though both these papers use assumptions and language particular to evolutionary epidemiology. We note that equation (2.5) in Parsons et al., 2018 is exactly equivalent to our stochastic replicator-mutator equation with no mutation (equation (S29) with $\lambda = 0$) upto a change in notation upon substituting the specific birth and death rate functions chosen in their paper into our equation (S29). Similarly, equation (5.1) in Day et al., 2020 is exactly equivalent to our stochastic Price equation for 2 species (equation (S38) with $m = 2$) if we write out w and τ in terms of per-capita birth and death rates. Our work can, therefore, be

used to recapitulate these results and show that the effects they illustrate are not particular to epidemiological models.

Lastly, noise-induced biases in population dynamics may also appear in the infinitesimal mean as a deviation from the expected trajectory if we project the ecological dynamics onto a ‘slow manifold’ through a separation of timescales argument, a common procedure for reducing the dimension of stochastic dynamical systems (Constable et al., 2013; Parsons and Rogers, 2017). A change of variables via a projection of the dynamics onto a manifold is responsible for the ‘noise-induced effects’ that appear in purely ecological models (i.e. models of population densities) where dynamics are projected onto a manifold describing populations that are at equilibrium over short timescales (Constable et al., 2016; Chotibut and Nelson, 2017; Mazzolini and Grilli, 2023). A change of variables via projection onto a manifold is also at the heart of the stochastic ‘drift-induced selection’ that drives evolutionary transitions between male and female heterogamety (XX/XY to ZW/ZZ and vice versa) in stochastic models of the evolution of chromosomal sex determination systems (Veller et al., 2017; Saunders et al., 2018). In models of sex determination, the projection is onto a manifold describing populations in which the sex ratio is 1:1 (Veller et al., 2017; Saunders et al., 2018). However, note that an additional stochastic term in a projected version of population densities need not lead to selection in the evolutionary sense, namely in terms of changes in trait frequencies (McLeod and Day, 2019).

S9 Connections with some other general frameworks

Our equations generalize Lion’s (2018) general framework of infinite population deterministic eco-evolutionary dynamics to finite, fluctuating populations — taking $K \rightarrow \infty$ in Eq. S29, Eq. S38, and Eq. S60 recover equations (6), (11), and (14) in Lion, 2018 respectively. Just like in the deterministic setting (Lion, 2018), equations for trait means (the Price equation, Eq. S38) and trait variances (Eq. S60) can be systematically derived from the equation for changes in trait frequencies (the replicator-mutator equation, Eq. S29) in our framework through repeated application of Itô’s

formula. If we assume that the quantity f follows a Gaussian distribution, then the mean and variance completely characterize the distribution, and thus, Eq. S29, Eq. S38, and Eq. S60 together specify the complete stochastic dynamics of the system.

Rice has proposed a stochastic version of the Price equation (Rice, 2020 and references cited therein). Like the original Price equation, Rice's equations are formulated as a general decomposition of the phenotypic change between two given populations. They are thus the true stochastic analog of the original Price equation, whereas our version, Eq. S38, is the analog of Lion's (2018) version of the Price equation in a continuous time, dynamically sufficient setting. Rice's derivations also treat fitness as fundamental, whereas we derive suitable notions of fitness and turnover from demographic first principles. As a consequence, the ‘extra’ stochastic term corresponding to noise-induced selection that appears in our equations fundamentally emerges from the stochasticity of the underlying births and deaths of organisms and is thus of ecological/demographic origin, whereas the ‘extra’ stochastic term in Rice’s equations emerges from the stochasticity of fitness alone when viewed as a random variable (Rice, 2020). It thus need not, to the best of our knowledge, correspond to the same effect we identify here.

There are also deep connections between the equations we present in this paper and those of Week et al. (2021). Informally, the equations presented in Week et al. (2021) can be recovered from our framework if we let the number of types m go to infinity and replace sums with integrals. Making this intuition precise is rather (mathematically) involved (Bhat, 2024), but we provide a summary of the idea below. We first require an intuitive explanation of how quantitative traits can be modeled in a stochastic birth-death framework.

Populations bearing discrete traits can be characterized by a vector $\mathbf{n} = [n_1, n_2, \dots, n_m]$ enumerating the number of individuals of each type. However, this cannot be done for populations bearing quantitative traits since infinitely many distinct types may arise. Instead, we characterize the population as a *finite measure* $\nu_t = \sum_{i=1}^{N(t)} \delta_{x_i}$ by placing a Dirac delta mass δ_{x_i} at the location x_i corresponding to the trait value of the i^{th} individual in a population consisting of $N(t)$ individuals at time t . The population dynamics can then be described in terms of a measure-valued stochastic

process (or, in physics language, a ‘stochastic field theory’) that tracks how ν_t evolves over time. Since we assume that every type has the same functional form for the birth and death rates, in the discrete case, the set of birth rate functions $\{b_i(\mathbf{n})\}_{i=1,2,\dots,m}$ (and analogously the death rate functions) can alternatively be viewed as a single function b from $\{1, 2, \dots, m\} \times [0, \infty)^m \rightarrow [0, \infty)$ whose i^{th} component gives us the birth rate of the i^{th} individual. This alternative view makes it clear what the analogous birth rate ‘function’ should look like for quantitative traits: The function b (and similarly the death rate function) is now replaced by a functional $B : \mathcal{T} \times \mathcal{M}(\mathcal{T}) \rightarrow [0, \infty)$, where $\mathcal{T} \subseteq \mathbb{R}$ is the trait space describing the set of allowed trait values and $\mathcal{M}(\mathcal{T})$ is the space of ‘functions’ (finite measures) on \mathcal{T} . One can then show that under some suitable assumptions, it is possible to carry out an analog of the ‘system size expansion’ we use in the supplementary of this manuscript to approximate the finite measure ν_t as a function $\phi(x, t)$ describing the distribution of population densities across the trait space. One can then derive stochastic partial differential equations (SPDEs) for how the distribution of trait frequencies, the mean value of any trait, and the variance of any trait change over time. These SPDEs end up being precisely the quantitative trait analogs of the SDEs we present in the main text (informally, the ‘ $m \rightarrow \infty$ limit’ of the m -dimensional system of SDEs we present in the main text of this manuscript).

With the broad outline explained above in mind, the connection of our equations with the equations presented in Week et al. (2021) can be made precise. Week et al. (2021) work with an asexual model with Gaussian mutation (their ‘SAGA’ - stochastic asexual Gaussian alleles). In their model, individuals give birth to offspring with mutations, with mutants normally distributed about the parent trait value with some small variance μ (their notation). Such mutation is approximated in their framework by the Laplacian of the function describing the distribution of population densities (i.e. as ‘diffusion’ across the trait space). Given a type x (an index i in the discrete case, now a real number that is also the trait value) in a population ϕ (a vector \mathbf{x} in the discrete case, now a function), the connection between our equations and Week et al. (2021)’s equations can be formally

made via the relations (our notation on the left, Week et al. (2021)'s notation on the right):

$$w_x(\phi) = m(x, \phi)$$

$$\tau_x(\phi) = V(x, \phi)$$

$$Q_x(\phi) = \frac{1}{2} \frac{\partial^2 \phi}{\partial x^2}$$

$$\lambda = \mu$$

(Compare Eq. 3 in our manuscript with Eq. 20 in Week et al. (2021)). Further, in the equation for the mean value (Their Eq. 21b, our Eq. S38) and variance (Their Eq. 21c, our Eq. S60) of a quantity, they restrict themselves to the special case $f_x(\phi) = x$, the quantitative trait analog of what in the discrete trait notation would be $f_i(\mathbf{x}) = i$. In this case, the influx terms of our equations will vanish for Week et al. (2021)'s choice of $Q_x(\phi)$. Formally, the influx terms in Eq. S38 and Eq. S60 are all integrals of the form

$$\int_{-\infty}^{\infty} (x - \bar{x})^k Q(x, \phi) dx = \frac{1}{2} \int_{-\infty}^{\infty} (x - \bar{x})^k \frac{\partial^2 \phi}{\partial x^2} dx$$

with either $k = 1$ or $k = 2$, and vanish upon using integration by parts and discarding the boundary terms. Thus, the influx terms do not contribute to the dynamics, which is why Eq. 21b in Week et al. (2021) corresponds to our Eq. S38 and Eq. 21c in Week et al. (2021) corresponds to our Eq. S60. A derivation of the quantitative trait analogs of the equations we present in this paper, along with a more precise explanation of the equivalence with Week et al., 2021, appears in Bhat, 2024.

S10 A more detailed explanation of the example in the main text

In this section, we flesh out the example introduced in Box 5 in more detail. To illustrate when noise-induced selection can be important for population dynamics, we use a simple biologically motivated example in this section. Several abiotic factors such as temperature and pH are known

to be ecological ‘rate modulators’ that affect either the birth rate or death rate of organisms, with obvious consequences for evolutionary dynamics (Fronhofer et al., 2023). To see how demographic stochasticity may affect the effect of ecological rate modulators on evolutionary dynamics, consider here two competing phenotypes, which we denote by 1 and 2. Though we stick to this ‘rate modulation’ language henceforth, another potential interpretation of the model we study below comes from epidemiology: In this case, the two types can be thought of as two competing strains of pathogens, a ‘rate modulator’ that affects birth rates can be thought of as affecting transmission rate, and a ‘rate modulator’ that affects death rates can be thought of as affecting virulence (Parsons et al., 2018). We consider the case where type 1 is affected by the ecological rate modulator but type 2 is not. For simplicity, we assume the population is closed with no mutations during birth (*i.e.* $\lambda = 0$). Below, we use p to denote the frequency of type 1 individuals in the population.

For pedagogical clarity, we assume that rate modulation occurs by simply shifting the birth and/or death rate by a constant. In equations, this can be modelled via the relations:

$$b_1^{(\text{ind})}(p, N_K) = b_2^{(\text{ind})}(p, N_K) + \epsilon_b \quad (\text{S91a})$$

$$d_1^{(\text{ind})}(p, N_K) = d_2^{(\text{ind})}(p, N_K) + \epsilon_d \quad (\text{S91b})$$

where ϵ_b and ϵ_d are real numbers describing the effect of the ecological rate modulator on the birth and death rates respectively. Using the definitions of s and κ , we find

$$s(p, N_K) = \epsilon_b - \epsilon_d \quad (\text{S92a})$$

$$\kappa(p, N_K) = -[\epsilon_b + \epsilon_d] \quad (\text{S92b})$$

Note that if $\epsilon_b = 0, \epsilon_d < 0$, both s and κ are positive, whereas if $\epsilon_b > 0, \epsilon_d = 0$, $s > 0$ but $\kappa < 0$. In other words, if type 1 has a decreased death rate (virulence in the epidemiological case) but identical birth rate relative to type 2, type 1 is favored by both natural selection and noise-induced selection. On the other hand, if type 1 has an increased birth rate (transmission

rate in the epidemiology case) but an identical death rate relative to type 2, type 1 is favored by natural selection but disfavored by noise-induced selection. Thus, all else being equal, reducing the death rate is generically more favorable than increasing the birth rate by an analogous amount, an observation that has been made in finite population models in epidemiology (Parsons et al., 2018), social evolution (McLeod and Day, 2019), life-history evolution (Alexander and Wahl, 2008), and cancer biology (Raatz and Traulsen, 2023).

For the rest of this example, we assume that $\epsilon_b > 0, \epsilon_d > 0$, *i.e.* that type 1 has both an increased birth rate and an increased death rate compared to type 2. We may now ask, when is the outcome of evolution different from that expected by infinite population dynamics?

Noise-induced biasing in the absence of natural selection

First, consider the situation $\epsilon_b = \epsilon_d = \epsilon$. This corresponds to the two types having the same growth rate, but type 1 having a faster pace of life than type 2. The selection coefficient and noise-induced selection coefficient are

$$s(p, N_K) = 0 \tag{S93}$$

$$\kappa(p, N_K) = -2\epsilon \tag{S94}$$

Thus, as expected, natural selection does not operate in the system. In the infinite population limit, natural selection is the only force that affects population dynamics and we thus expect any initial frequency p_0 of type 1 individuals to remain unchanged in the population (to see this, take $K \rightarrow \infty$ in Eq. 9). Over short timescales, the effects of demographic stochasticity can be observed by looking at the expected change in frequency $\mathbb{E}[dp]$. Using Eq. 9 and substituting the functional forms given by Eq. S92, we find

$$\frac{d}{dt} \mathbb{E}[p] = \mathbb{E} \left[\frac{\kappa(p, N_K)}{N_K} p(1-p) \right] = -\frac{2\epsilon}{KN_K} \mathbb{E}[p(1-p)] \tag{S95}$$

Since the RHS of Eq. S95 is always negative for $p \in (0, 1)$, we can infer that if the system begins at any initial frequency $p_0 \in (0, 1)$, the proportion of type 1 individuals is expected to decrease on average. If $\epsilon_b = \epsilon_d$, the ecological rate modulator is thus detrimental to the evolutionary fate of type 1 individuals over short time scales in finite populations, despite infinite population models predicting neutrality. This result is a manifestation of the ‘direct’ mechanism of noise-induced biasing via the Gillespie effect (noise-induced selection): All else being equal, a faster pace of life comes with a greater variance in change of population density within a given time interval since there are simply more stochastic birth/death events taking place.

However, the speed density S77 depends not only on the expected change of frequency alone but also on the variance in the change of frequencies. This stochastic effect, captured by the dW term in Eq. 9, depends on the functional form of $\tau_1(p, N_K)$ (and not merely the difference $\kappa = \tau_2 - \tau_1$), which we have not yet specified in our model (Eq. S91). For simplicity, let us assume that the turnover rates τ_i depend linearly on p . Specifically, let us assume that $\tau_1(p, N_K) = bp + c$, where b and c are constants. c can be viewed as an ‘intrinsic’ turnover rate, and b as a frequency-dependent component that may be either positive or negative. We are therefore restricting ourselves to linear frequency dependence of τ_1 , but allowing both positive and negative frequency-dependence, with the strength of frequency-dependence controlled by $|b|$. For convenience, let $a = 2\epsilon_d = -\kappa(p)$. Note that since τ_1 is the sum of two rates and $p(1-p)V(p)$ is the infinitesimal variance of the trait frequency SDE, the parameters a, b , and c must be chosen such that $\tau_1(p) = bp + c > 0, V(p) = (b-a)p + c > 0 \forall p \in [0, 1]$ for the system to be biologically meaningful. In particular, $\tau_1(0, N_K)$ and $\tau_1(1, N_K)$ must be non-negative, and we must thus have $\tau_1(0, N_K) = c \geq 0$ and $\tau_1(1, N_K) = b + c > 0$. We must also have $V(1) > 0$, and thus $b + c - a \geq 0$.

Since we would like κ to still be given by Eq. S94, this automatically specifies τ_2 as $\tau_2 = bp + c - 2\epsilon$. Thus, we assume τ_1 and τ_2 change in the same direction (increase or decrease) as the frequency of type 1 individuals increases.

In this case, we can exactly solve for the speed density. Note that we have

$$E(p) = -\frac{2\epsilon_d}{KN_K} \quad (\text{S96})$$

$$V(p) = \frac{1}{KN_K}(\tau_1(p, N_K) - 2\epsilon_d p) \quad (\text{S97})$$

where $a = 2\epsilon_d = -\kappa(p)$. In our new notation, Eq. S96 and S97 become

$$E(p) = -\frac{a}{KN_K} \quad (\text{S98})$$

$$V(p) = \frac{1}{KN_K}((b-a)p + c) \quad (\text{S99})$$

The speed density of the system can be written (from Eq. S82) as

$$\begin{aligned} m(p) &= \frac{1}{p(1-p)V(p)} \exp \left(2 \int^p \frac{E(q)}{V(q)} dq \right) \\ \Rightarrow m(p) &= \frac{KN_K}{p(1-p)((b-a)p + c)} \exp \left(2a \int^p \frac{1}{(b-a)q + c} dq \right) \end{aligned} \quad (\text{S100})$$

We need to distinguish between two cases based on whether or not V is frequency-dependent.

Case 1: No frequency dependence in $V(p)$

If $a = b$, i.e. the frequency dependence of τ_1 is positive with strength exactly equal to $2\epsilon_d$, Eq. S100 becomes

$$m(p) = \frac{1}{p(1-p)c} \exp \left(2 \int^p \frac{-a}{c} dq \right) = C \frac{1}{p(1-p)} e^{-\alpha p} \quad (\text{S101})$$

where $\alpha = 2a/c > 0$ is a positive constant, and we use C to denote a constant whose precise value is irrelevant (and thus may change from line to line below — the important thing is that C does not depend on p and thus plays the role of a normalization constant).

The shape of the distribution given by Eq. S101 can be thought of as the combination of two components: The term $p(1-p)$ is symmetric with respect to the transformation $p \rightarrow 1-p$ (i.e.

symmetric about $p = 0.5$) and thus does not favour either type of individual, whereas $e^{-\alpha p}$ is a strictly decreasing function of p and thus always favours lower frequencies of type 1 individuals. If α is very small, the effect of $e^{-\alpha p}$ is negligible and the distribution of types is approximately a symmetric ‘U-shaped’ parabola centered at 0.5, with $p = 0.5$ being the least likely frequency. This is the expectation we would have if neutral genetic drift was the only force at play: The distribution is (approximately) symmetric with respect to the transformation $p \rightarrow 1 - p$, with $p = 0$ and $p = 1$ being the most likely states and $p = 0.5$ being the least likely state.

If, instead, α is not small, the function $e^{-\alpha p}$ decays quickly and biases the distribution towards lower values of p . In this case, the function is a distorted U-shape, with the minimum point being somewhere in $(1/2, 1)$. The extent of bias towards lower values of p increases as α increases.

Thus, in the case where $2\epsilon_d = d\tau_1/dp$, we can conclude that lower frequencies of type modulators are always associated with a higher speed density, and the biasing is stronger as the ratio of the rate modulation (ϵ_d) to the intrinsic frequency-independent turnover rate (c) increases. Note that the shape of the speed density (and thus the extent of deviation from neutrality in terms of time spent/liability of observation conditioned on non-fixation) does *not* depend on the total population size KN_K .

Case 2: Frequency dependence in $V(p)$

Assuming $a \neq b$, we can calculate the exponential term in Eq. S100 as

$$\exp \left(2 \int^p \frac{E(q)}{V(q)} dq \right) = \exp \left(-2a \int^p \frac{1}{(b-a)q + c} dq \right) \quad (\text{S102})$$

$$= C \exp \left(-\frac{2a}{b-a} [\log((b-a)p + c)] \right) = C[(b-a)p + c]^{-\frac{2a}{b-a}} \quad (\text{S103})$$

where we once again use C to denote a multiplicative constant whose precise value is irrelevant.

Thus, the speed density S100 is given by

$$m(p) = \frac{C}{p(1-p)} [(b-a)p + c]^{-(\gamma+1)} \quad (\text{S104})$$

where we have defined $\gamma = 2a/(b - a)$.

Equations S101 and S104 are exact solutions for the speed density, and are the quantities plotted in Figure II in Box 5. For convenience, we reproduce the figure below

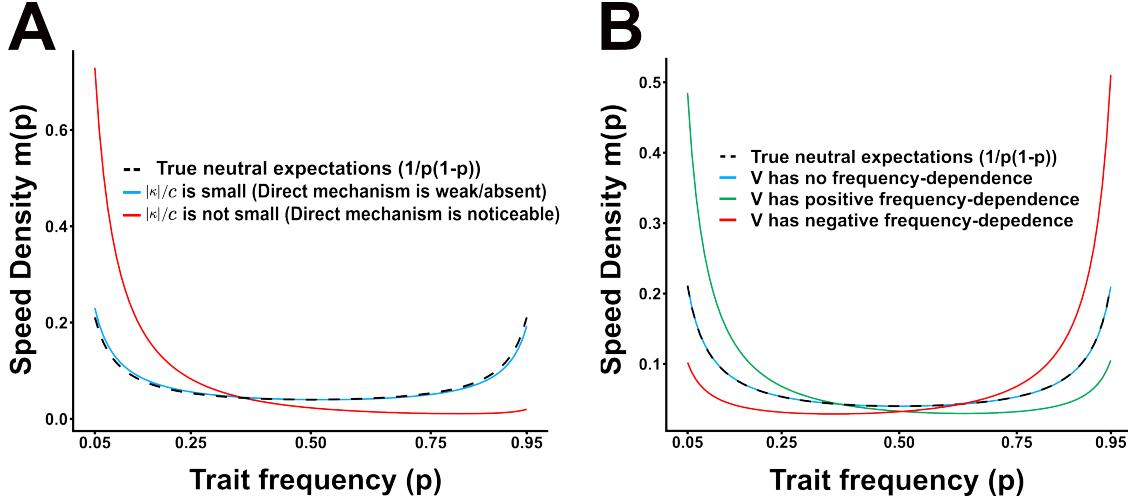

Figure S1: Two distinct noise-induced effects that bias evolutionary dynamics. **A.** If the magnitude of the noise-induced selection coefficient $\kappa = -2\epsilon$ is large relative to the intrinsic turnover rate c , the direct mechanism of noise-induced biasing operates. Parameters are chosen such that $V(p) = \tau_1 + p\kappa = (b - 2\epsilon)p + c$ is not frequency-dependent (blue: $\epsilon = 0.5, b = 1, c = 10$; red: $\epsilon = 0.5, b = 1, c = 0.5$). **B.** The speed density can also be biased if $V(p)$ is frequency-dependent. This indirect mechanism of noise-induced biasing favours the type that reduces $V(p)$. Parameters in this panel are chosen such that $|\kappa|$ is small relative to c and thus the strength of the fast mechanism is negligible (blue: $\epsilon = 0.025, b = 0.05, c = 10$; green: $\epsilon = 0.025, b = 50, c = 10$; red: $\epsilon = 0.025, b = -8.5, c = 10$)

Figure S1 illustrates two distinct ways in which stochasticity alone can bias trait frequency distributions in finite, fluctuating populations. If dynamics are truly neutral (in the sense of the two types being exactly equivalent) and the system begins with $p = 0.5$, then both types are equally likely to increase/decrease. The speed density is thus equal to $1/p(1 - p)$ (up to a constant). Noise-induced effects can bias this distribution in two distinct ways (Box 4): (1) The noise-induced selection coefficient κ can bias the expected trajectory. This is noise-induced selection and can be identified with the Gillespie effect from bet-hedging theory as a selection for reduced variance in density change dx_i . Since $\kappa = -2\epsilon < 0$, noise-induced selection always favours the type with the slower pace of life (Fig. S1A). (2) A second noise-induced effect appears as a biasing of the speed density via the last term of Eq. 10. We call this an ‘indirect’ mechanism of bias because it is not

observable in terms of expectations $\mathbb{E}[\cdot]$ but is visible in terms of time spent in various states. For our example, we can calculate

$$\begin{aligned} V(p) &= \tau_1 + p\kappa = bp + c + p\kappa \\ \Rightarrow \frac{dV}{dp} &= b - \kappa \end{aligned} \tag{S105}$$

Equation S105 tells us that this indirect mechanism favours type 1 if $b < \kappa$, type 2 if $b > \kappa$, and does not operate if $b = \kappa$. Thus, the indirect mechanism may cause biases in either the same direction or the opposite direction of noise-induced selection based on the details of the frequency-dependence of the per-capita turnover rates (Fig S1B).

Noise-induced biasing in the presence of natural selection

Consider now instead a situation in which the rate modulator affects the birth rate more than it does the death rate (*i.e.* $\epsilon_b > \epsilon_d > 0$). In this case, the selection coefficient s in Eq. S92 is always positive, and thus natural selection always favors type 1 individuals. As before, noise-induced biases may manifest in two distinct ways. First, noise-induced selection may invert the direction of the expected trajectory $\mathbb{E}[dp/dt]$. Noise-induced biasing may also occur through the indirect mechanism. We examine the two possibilities one by one.

Since $s > 0$, we can use Eq. 9 to say the expected trajectory is in the opposite direction of infinite population predictions if $s + \kappa/KN_K < 0$. Using Eq. S92, we see that this is equivalent to

$$\begin{aligned} \epsilon_b - \epsilon_d - \frac{1}{KN_K} (\epsilon_b + \epsilon_d) &< 0 \Rightarrow \left(1 - \frac{1}{KN_K}\right) \epsilon_b < \left(1 + \frac{1}{KN_K}\right) \epsilon_d \\ \Rightarrow \frac{\epsilon_b}{\epsilon_d} &< \frac{KN_K + 1}{KN_K - 1} \end{aligned} \tag{S106}$$

Using inequality S106 in Eq. S92a, we can arrive at the inequality

$$\begin{aligned} s = \epsilon_d \left(\frac{\epsilon_b}{\epsilon_d} - 1 \right) &< \epsilon_d \left(\frac{KN_K + 1}{KN_K - 1} - 1 \right) \\ \Rightarrow s(KN_K - 1) &< 2\epsilon_d \end{aligned} \quad (\text{S107})$$

Thus, noise-induced selection can reverse the expected trajectory of evolutionary dynamics when the product $s(KN_K - 1)$ is sufficiently small, *i.e.* when either *selection is weak* (s is small), *populations are small* (KN_K is small), or both.

We now also examine the contributions of the noise terms to the speed density. We see from Eq. 10 that we can say type 1 is favoured by the indirect mechanism when $dV/dp < 0$. Using the definition of V from Eq. 11b and substituting the functional forms given by Eq. S92, we see that $dV/dp < 0$ is equivalent to

$$\frac{d\tau_1}{dp} < \epsilon_b + \epsilon_d \quad (\text{S108})$$

If τ_1 is a constant, *i.e.* the per-capita birth rates $b_1^{(\text{ind})}$ and $d_1^{(\text{ind})}$ do not depend on population composition, inequality S108 will automatically be satisfied as long as there is some rate modulation in the system (*i.e.* ϵ_b and ϵ_d are not both 0). If τ_1 is frequency dependent, S108 is satisfied whenever τ_1 exhibits negative frequency dependence, though it may also be satisfied if τ_1 exhibits weak positive frequency dependence. We do not explore the effects of the indirect mechanism further for the sake of conciseness. However, we note that since we already studied the behaviour of $E(p)$ above, it is now straightforward to determine from Eq. 10 when this latter effect combines with $E(p)/V(p)$ to make the RHS of Eq. 10 positive. In Supplementary section S11, we provide an example system in which noise-induced selection can never reverse the expected trajectory $\mathbb{E}[dp/dt]$, but where the indirect mechanism of noise-induced biasing may nevertheless affect the distribution of types in the population. In Supplementary section S12, we provide an example of a stochastic Lotka-Volterra competition model with both natural selection and mutation in which noise-induced selection can reverse the direction of evolution predicted by natural selection-mutation balance.

S11 An example in which noise-induced selection can never reverse the direction of evolution over short timescales, but where the indirect mechanism may still operate

Consider a slightly modified version of the example covered in the main text. Consider here two types in which rate modulation decreases the birth rate and increases the death rate of type 1 individuals. In equations, such modulation can be modelled via the relations:

$$b_1^{(\text{ind})}(p, N_K) = b_2^{(\text{ind})}(p, N_K) - \epsilon_b \quad (\text{S109a})$$

$$d_1^{(\text{ind})}(p, N_K) = d_2^{(\text{ind})}(p, N_K) + \epsilon_d \quad (\text{S109b})$$

where ϵ_b and ϵ_d are non-negative real numbers describing the effect of the ecological rate modulator on the birth and death rates respectively. Note that in this case, ϵ_b cannot be arbitrarily large: we require $\epsilon_b \leq \inf_{\substack{p \in [0,1] \\ N_K \geq 0}} \{b_2^{(\text{ind})}(p, N_K)\}$ to avoid negative birth rates. As in the main text, we can calculate the selection coefficient and noise-induced selection coefficient to find

$$s(p, N_K) = -[\epsilon_b + \epsilon_d] \quad (\text{S110a})$$

$$\kappa(p, N_K) = \epsilon_b - \epsilon_d \quad (\text{S110b})$$

Here, s is always negative whenever there is some rate modulation in the system (*i.e.* ϵ_b and ϵ_d are not both 0), and thus natural selection always favors type 2 over type 1. Note that here, when evolution is neutral with respect to natural selection ($s = 0$), we must have $\epsilon_b = \epsilon_d = 0$. In this case, $b_1^{(\text{ind})}(p, N_K) = b_2^{(\text{ind})}(p, N_K)$ and $d_1^{(\text{ind})}(p, N_K) = d_2^{(\text{ind})}(p, N_K)$, and thus the two types are exactly equivalent in every respect.

We first examine when the sign of $\mathbb{E}[dp/dt]$ is reversed relative to infinite population expectations, *i.e.* when noise-induced selection can reverse evolutionary outcomes. Since $s < 0$, we can use

Eq. 9 to say the expected trajectory is in the opposite direction of infinite population predictions if $s + \kappa/KN_K > 0$. Using Eq. S110, we see that this is equivalent to

$$-[\epsilon_b + \epsilon_d] + \frac{1}{KN_K} (\epsilon_b - \epsilon_d) > 0 \Rightarrow \left(1 - \frac{1}{KN_K}\right) \epsilon_b + \left(1 + \frac{1}{KN_K}\right) \epsilon_d < 0 \quad (\text{S111})$$

$$\Rightarrow \frac{\epsilon_b}{\epsilon_d} < -\frac{KN_K + 1}{KN_K - 1} < 0 \quad (\text{S112})$$

Since ϵ_b and ϵ_d are both non-negative, so is their ratio, and thus inequality S112 can never be satisfied. We therefore conclude that noise-induced selection *cannot* reverse the sign of $\mathbb{E}[dp/dt]$ relative to infinite population expectations in this case.

However, the speed measure may still be biased due to the indirect mechanism. We see from Eq. 10 that type 1 may be favoured via the indirect mechanism if dV/dp is sufficiently negative. Using the definition of V from Eq. 11b, we see that dV/dp is negative whenever

$$\frac{d\tau_1}{dp} < \epsilon_b - \epsilon_d \quad (\text{S113})$$

Note, however, that for this system, since $E(p)$ will always be positive, $dV/dp < 0$ is a necessary but not a sufficient condition for deviation from infinite population expectations — we also require dV/dp to be large enough in magnitude relative to $E(p)$ to ensure that the RHS of Eq. 10 as a whole becomes positive.

S12 An example of non-neutral competition where evolution does not proceed in the direction of natural selection due to noise-induced effects

In this section, we provide an example of resource competition with both natural selection and mutation in which noise-induced selection reverses the direction of evolution predicted by natural selection.

Consider a community that contains two types of birds, say type 1 and type 2. These birds compete for limited resources, but in a peculiar manner: Though the two birds feed on different food sources, the trees that type 1 birds use for nesting are the same as those that the type 2 birds rely on for food. Both types are territorial and do not tolerate other individuals of either type on either their nesting or feeding sites. Thus, competition between the two types affects the *birth rate* of type 1 birds (because they can't find good nesting sites) but the *death rate* of type 2 birds (due to starvation), whereas intratype competition affects the death rate in both cases due to competition for food sources. We also assume that when individuals give birth, they may give birth to offspring of the opposite type (due to mutations) at a rate $\lambda > 0$. Thus, the influx rate λ here is a mutation rate, and we will therefore denote it by $\lambda = \mu$ to align with standard notational conventions. Let n_i be the number of type i individuals (which may vary over time). Assuming trees and birds are both randomly distributed through the landscape and the population dynamics of birds has linear density dependence, the simplest model that can incorporate these features of resource competition is given by:

$$\begin{aligned} b_1(n_1, n_2) &= n_1 - (1 + \epsilon) \frac{n_1 n_2}{K} + \mu n_2 & ; \quad d_1(n_1, n_2) &= \frac{n_1^2}{K} \\ b_2(n_1, n_2) &= n_2 + \mu n_1 & ; \quad d_2(n_1, n_2) &= \frac{n_2^2}{K} + \frac{n_1 n_2}{K} \end{aligned} \tag{S114}$$

where K is a carrying capacity for the habitat, similar to Lotka-Volterra competition, and ϵ is a parameter, which as we shall see below, quantifies which type has a competitive advantage. Note that ϵ must be chosen such that $b_1(n_1, n_2)$ is always non-negative.

Moving to density space via the change of variables $x_i = n_i/K$, letting $\mathbf{x} = [x_1, x_2]^\top$, and comparing terms with Eq. S4, we see that the per-capita fitness w_i of each type is:

$$w_1(\mathbf{x}) = 1 - x_1 - (1 + \epsilon)x_2 = 1 - pN_K - (1 + \epsilon)(1 - p)N_K$$

$$w_2(\mathbf{x}) = 1 - x_1 - x_2 = 1 - pN_K - (1 - p)N_K$$

where $N_K = x_1 + x_2$ is the (scaled) total population size and $p = x_1/N_K$ is the frequency of type 1 individuals in the population. In frequency space, we thus see that the selection coefficient

$s := w_1 - w_2$ is given by

$$s(p, N_K) = -\epsilon(1 - p)N_K \quad (\text{S115})$$

This calculation makes it clear that ϵ controls the strength and direction of natural selection operating in the system — when $\epsilon > 0$, natural selection favors type 2, whereas when $\epsilon < 0$, type 1 is favored. When $\epsilon = 0$, the two types of birds have the same fitness and there is no natural selection operating in the system. If we now compute the per-capita turnover rates τ_i of each type, we have

$$\begin{aligned}\tau_1(\mathbf{x}) &= 1 + x_1 - (1 + \epsilon)x_2 = 1 + pN_K - (1 + \epsilon)(1 - p)N_K \\ \tau_2(\mathbf{x}) &= 1 + x_1 + x_2 = 1 + N_K\end{aligned}$$

and the noise-induced selection coefficient $\kappa := \tau_2 - \tau_1$ is therefore

$$\kappa(p, N_K) = (2 + \epsilon)(1 - p)N_K \quad (\text{S116})$$

Note that when $\epsilon = 0$, s vanishes but κ does not, meaning that the system exhibits noise-induced selection but no natural selection. Further, whenever $\epsilon > 0$ or $\epsilon < -2$, s and κ have opposite signs, *i.e.* natural selection and noise-induced selection act in opposite directions. Here, focusing on the case $\epsilon > 0$, we see from Eq. S115 that natural selection favors type 2, whereas Eq. S116 tells us that noise-induced selection favors type 1.

Finally, we also have $Q_1(\mathbf{p}) = (1 - p)$, $Q_2(\mathbf{p}) = p$. Substituting all these functional forms into Eq. S29 now tells us (after some algebra) that the frequency of type 1 individuals in the population obeys the SDE

$$dp = \left[p(1-p)^2 \left[\frac{2}{K} - \epsilon \left(N_K(t) - \frac{1}{K} \right) \right] + \mu(1-2p) \left(1 - \frac{1}{KN_K(t)} \right) \right] dt + \frac{1}{\sqrt{KN_K(t)}} \sqrt{p(1-p) [1 + N_K(t) (1 - (2+\epsilon)(1-p)^2)] + \mu [1 - 3p(1-p)]} dW_t \quad (\text{S117})$$

where W_t is a one-dimensional Wiener process. Upon substituting our functional forms of fitness and turnover into Eq. 7, we find that the total scaled total population size N_K obeys the SDE

$$\frac{1}{N_K} dN_K = [1 + \mu - N_K (1 + \epsilon p(1-p))] dt + \frac{1}{\sqrt{KN_K}} \sqrt{1 + \mu + N_K (1 - \epsilon p(1-p))} dW_t^{N_K} \quad (\text{S118})$$

where $W_t^{N_K}$ is a one-dimensional Wiener process. We are now in a position to study the behaviour of this system.

The infinite population limit

If we let $K \rightarrow \infty$, the SDE for type frequency given by Eq. S117 reduces to an ODE

$$\frac{dp}{dt} = -\epsilon N_K p(1-p)^2 + \mu(1-2p) \quad (\text{S119})$$

When there is no mutation and no selection in the system ($\mu = \epsilon = 0$), the RHS of Eq. S119 vanishes, and thus, any initial trait frequency p_0 is expected to remain unchanged forever. If we switch off mutation alone ($\mu = 0, \epsilon \neq 0$), it is easy to check that the type favoured by selection will become fixed in the population. Instead, if we switch off selection alone ($\mu \neq 0, \epsilon = 0$), mutations drive the population to a state in which both types are equally prevalent (i.e., $p = 0.5$). When both selection and mutation are present in the system, the stable fixed point in the infinite population limit will lie in $(0, 1/2)$ when $\epsilon > 0$, and will lie in $(1/2, 1)$ when $\epsilon < 0$.

Deviations from neutrality due to noise-induced selection in finite, fluctuating populations

The effects of noise-induced selection on the expected dynamics are clearest when there is no natural selection ($\epsilon = 0$) and no mutation ($\mu = 0$): In this case, the equation for trait frequencies (Eq. S117) becomes

$$dp = \frac{2p(1-p)^2}{K} dt + \frac{1}{\sqrt{KN_K(t)}} \sqrt{p(1-p)[1 + N_K(t)(1 - 2(1-p)^2)]} dW_t \quad (\text{S120})$$

If we now take expectations on both sides, the stochastic integral term vanishes and we obtain an ODE for the expected trait frequency in the population. This ODE takes the form

$$\frac{d}{dt} \mathbb{E}[p] = \frac{2}{K} \mathbb{E}[p(1-p)^2] \quad (\text{S121})$$

Since the RHS is always positive for $p \in (0, 1)$, we conclude that the frequency of type 1 birds is always expected to increase until type 1 becomes fixed in the population. Thus, noise-induced selection, in this case, has led to a deviation from evolutionary neutrality in the expected dynamics — in the infinite population case, any initial trait frequency p_0 is expected to remain unchanged forever, whereas for finite, fluctuating populations, assuming $p_0 \notin \{0, 1\}$, the trait frequency of type 1 birds is expected to increase until type 1 eventually fixes in the population. Note that unlike in neutral drift, type 1 is *always* expected to be the type that becomes fixed in the population despite the two types having the same fitness.

Reversal of the direction of evolution in finite, fluctuating populations

For the birth-death processes of the type we study in this paper, the entire population will go extinct in finite time with probability 1 (Ethier and Kurtz, 1986). Thus, the true stationary distribution for our system is thus the trivial state $x_1 = x_2 = 0$, a state at which p is undefined. However, the expected time to extinction is often so large as to be biologically meaningless, and in such cases, we can instead speak of the ‘quasi-stationary distribution’ of the stochastic process,

obtained by only examining the system before the population goes extinct (Ethier and Kurtz, 1986; Karlin and Taylor, 1981). Thus, we are interested in the behaviour of the system in (p, N_K) space conditioned on $N_K > 0$. To study the behaviour of the trait frequency when the population is far from extinction, we simply use the naive assumption $N_K \equiv 1$ to arrive at an approximate description of the system. As an aside, we note that better approximations could be made via the so-called ‘weak noise approximation’ or ‘linear noise approximation’ (Van Kampen, 1981; Black and McKane, 2012), though we do not do so here. Under the approximation $N_K \equiv 1$, the speed density $m(p)$ is given by (see Supplementary section S6)

$$m(p) = \frac{\mathcal{N}}{G(p)} \exp \left(\int_0^p \frac{F(q)}{G(q)} dq \right) \quad (\text{S122})$$

where \mathcal{N} is a normalization constant and F and G are functions given by

$$\begin{aligned} F(p) &:= p(1-p)^2 [2 - \epsilon(K-1)] + \mu(1-2p)(K-1) \\ G(p) &:= p(1-p) (2 - (2+\epsilon)(1-p)^2) + \mu(1-3p(1-p)) \end{aligned} \quad (\text{S123})$$

Since the above solution is an approximation, we also conduct exact stochastic individual-based simulations of the complete system defined by Eq. S114 using the Gillespie algorithm. The results of the simulations, as well as the solution predicted by Eq. S122, are plotted for a small $\epsilon > 0$ (corresponding to weak selection against type 1) in figure S2.

For low values of K and ϵ , both the stochastic individual-based simulations and the approximate solution given by Eq. S122 indicate that noise-induced selection causes the distribution of types in the population to be biased in favor of type 1 (rightmost peak in Fig S2A) despite natural selection-mutation balance predicting a polymorphism in which type 2 individuals are over-represented. This bias disappears when K and ϵ are high, i.e. populations are large and natural selection is strong (Fig S2B).

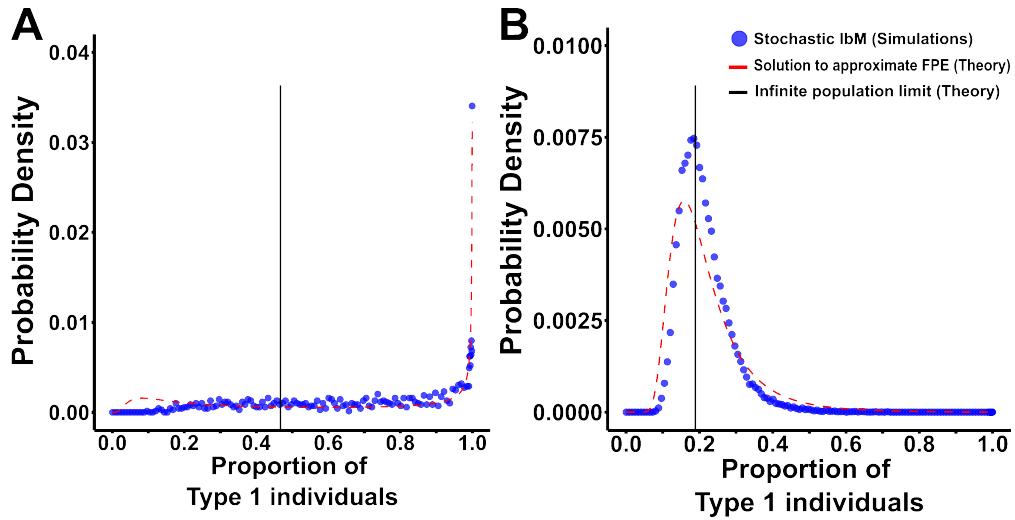

Figure S2: Predictions of our resource-competition model for various parameters. The quasi-stationary distribution has been plotted for (A) $K = 500, \epsilon = 0.0005$, and (B) $K = 5000, \epsilon = 0.005$. Blue points are from 100 independent Gillespie simulations of the exact birth-death process defined by Eq. S114, each supplied with the initial condition $n_1 = n_2 = K/2$ and allowed to run for 10^5 timesteps or until the complete population went extinct. The red dotted line is derived from numerically evaluating the RHS of equation Eq. S122. The solid black line is the infinite population limit, obtained by solving equation Eq. S119 under the approximation $N_K \equiv 1$. For all plots in this figure, $\mu = 0.01$.
